Introduction

There have been two major methods employed in the use of psychedelic or mind-opening drugs (LSD, psilocybin, and mescaline, to name the major ones) in order to obtain the maximal therapeutic effect in psychiatric patients. The first method involves a small dose technique (25 to 100 mcg of LSD) in weekly or bi-weekly sessions to facilitate the release of unconscious material and aid psychotherapy or group therapy. This method is the predominant one used by LSD therapists in Europe.

Sandison and Spencer[1] pioneered this method and are continuing their work which stresses abreaction. Spencer[2] has recently written a review of modifications. Ling and Buckman[3] in their book have outlined their technique and have given representative case histories. Martin[4, 5] has employed LSD in the framework of a psychoanalytic approach. Leuner[6, 7] in Germany has been a leader on the continent. Van Rhijn[8] and Hein[9, 10] have been continuing and expanding their interest in LSD therapy in Holland. In Belgium, Aguilar[11] has used psilocybin with in-patients who receive intensive supervision and psychotherapy before, during, and after drug sessions. Alhadeff[12] in Switzerland has also found psilocybin useful as an adjunct to psychotherapy. In Sweden, Kaij[13] has employed an LSD technique which is similar to that used by Sandison and Spencer in England. Alnaes[14] has compiled a bibliography of the Danish and Norwegian LSD literature. Although not so much work is currently in progress in the United States, there have been clinicians who have advocated a similar approach with some modifications in technique.[15, 16, 17, 18]

The second method involves a much smaller number of psychedelic drug sessions or even a single one, but at a higher dosage in order to produce an experience with such an overwhelming impact as to change radically the patient's view of the world and himself in a healthful and therapeutic manner. Descriptions of this method have been written by Chwelos and coworkers,[19] MacLean and coworkers,[20] and Sherwood and coworkers.[21] See also Unger's excellent review article[22] and his description of the English language literature.[23] The striking similarity of some of these drug experiences to the reports given by mystics from many varying cultures and epochs has led some investigators to consider the possible use of this kind of drug experience as an aid in psychotherapy. Research in the psychology of religion may be of value in illuminating the second approach. Data from such research will be presented as an example of this possibility.

Examination of the Claim that Psychedelic Drug Experience May Resemble Mystical Experience

There is a long and continuing history of the religious use of plants which contain psychedelic substances. Scholars such as Osmond,[24] Schultes,[25] and Wasson[26] have made valuable contributions to this intriguing field. In some instances, such natural products were ingested by a priest, shaman, or witch doctor to induce a trance for revelatory purposes; sometimes they were taken by groups of people who participated in sacred ceremonies. For example, the dried heads of the peyote cactus, whose chief active ingredient is mescaline, were used by the Aztecs at least as early as 300 B.C. and are currently being employed by over 50,000 Indians of the North American Native Church as a vital part of their religious ceremonies. Both *ololiuqui*, a variety of morning glory seed, and certain kinds of Mexican mushrooms (called *teonanacatl*, "flesh of the gods") were also used for divinatory and religious purposes by the Aztecs. These practices have continued to the present among remote Indian tribes in the mountains of Oaxaca Province in Mexico. Modern psychopharmacological research has shown the active chemicals to be psilocybin in the case of the mushrooms, and several compounds closely related to LSD in the case of *ololiugui*. *Amanita muscaria*, the mushroom which has been used for unknown centuries by Siberian shamans to induce religious trances, does not contain psilocybin. The most important psychologically active compound from this mushroom has not yet been isolated, but promising work is in progress. Other naturally occurring plants used by various South American Indian tribes in a religious manner for prophecy, divination, clairvoyance, and the tribal initiation of male adolescents, or sacred feasts, are cohoba snuff made from the pulverized seeds of *Piptadenia*, the drink, *vinho de Jurumens*, made from the seeds of *Mimosa hostilis*, and the drink, caapi, made from *Banisteriopsis*. These last three products contain various indolic compounds closely related to psilocybin, both structurally and in their psychic effects (bufotenine, dimethyltryptamine, harmine). Both LSD and psilocybin contain the indolic ring, and mescaline may be metabolized to an indole in the body.

An empirical study, designed to investigate in a systematic and scientific way the similarities and differences between experiences described by mystics and those induced by psychedelic drugs, was undertaken by the author.[27] First, a phenomenological typology of the mystical state of consciousness was carefully defined after a study of the writings of the mystics themselves and of scholars who have tried to characterize mystical experience. Then, some drug experiences were empirically studied, not by collecting such experiences wherever an interesting or striking one might be found and analyzed after the fact, but by conducting double-blind, controlled experiments with subjects whose religious background and experience, as well as personality, had been measured *before* their drug experiences. The preparation of the subjects, the setting under which the drug was administered, and the collection of data about the experience were made as uniform as possible. The experimenter himself devised the experiment, collected the data, and evaluated the results without ever having had an experience with any of these drugs.

A nine-category typology of the mystical state of consciousness was defined as a basis for measurement of the phenomena of the psychedelic drug experiences. Among the numerous scholars of mysticism, the work of W. T. Stace[20] was found to be the most helpful guide for the construction of this typology. His conclusion that in the mystical experience there are certain fundamental characteristics which are universal and not restricted to any particular religion or culture (although particular cultural, historical or religious conditions may influence both the interpretation and description of these basic phenomena) was taken as a presupposition. Whether or not the mystical experience is "religious" depends upon one's definition of religion and was not the problem investigated. Our typology defined the universal phenomena of the mystical experience, whether considered "religious" or not.

The nine categories of our phenomenological typology may be summarized as follows:

Category I: Unity

Unity, the most important characteristic of the mystical experience, is divided into internal and external types, which are different ways of experiencing an undifferentiated unity. The major difference is that the internal type finds unity through an "inner world" within the experiencer while the external type finds unity through the external world outside the experiencer.

The essential elements of internal unity are loss of usual sense impressions and loss of self without becoming unconscious. The multiplicity of usual external and internal sense impressions (including time and space) and the empirical ego or usual sense of individuality, fade or melt away while consciousness remains. In the most complete experience this consciousness is a pure awareness beyond empirical content, with no external or internal distinctions. In spite of the loss of sense impressions and dissolution of the usual personal identity or self, the awareness of oneness or unity is still experienced and remembered. One is not unconscious, but rather very much aware of an undifferentiated unity.

External unity is perceived outwardly with the physical senses through the external world. A sense of underlying oneness is felt behind the empirical multiplicity. The subject or observer feels that the usual separation between himself and an external object (inanimate or animate) is no longer present in a basic sense, yet the subject still knows that on another level, at the same time, he and the objects are separate. Another way of expressing this same phenomenon is that the essences of objects are experienced intuitively and felt to be the same at the deepest level. The subject feels a sense of oneness with these objects because he "sees" that at the most basic level all are part of the same undifferentiated unity. The capsule statement, "all is one," is a good summary of external unity. In the most complete experience, a cosmic dimension is felt so that the experiencer feels, in a deep sense, a part of everything that is.

Category II: Transcendence of Time and Space

This category refers to loss of the usual sense of time and space. This means clock time but may also be one's personal sense of his past, present, and future. Transcendence of space means that a person loses his usual orientation as to where he is during the experience in terms of the usual three-dimensional perception of his environment. Experiences of timelessness and spacelessness may also be described as an experience of "eternity" or "infinity."

Category III: Deeply Felt Positive Mood

The most universal elements (and, therefore, the ones which are most essential in the definition of this category) are joy, blessedness and peace. Their unique character in relation to the mystical experience is that their intensity marks them as being at the highest levels of the human experience of these feelings, and they are valued highly by the experiencers. Tears may be associated with any of these elements because of the overpowering nature of the experience. These feelings may occur at the peak of the experience or during the "ecstatic afterglow" when the peak has passed, but its effects and memory are still quite vivid and intense. Love may also be an element of deeply felt positive mood, but does not have the same universality as joy, blessedness, and peace.

Category IV: Sense of Sacredness

This category comprises the sense of sacredness which is evoked by the mystical experience. The sacred is here defined broadly as that which a person feels to be of special value and capable of being profaned. The basic characteristic of sacredness is a non-rational, intuitive, hushed, palpitant response of awe and wonder in the presence of inspiring realities. No religious "beliefs" or traditional theological terminology need necessarily be involved, even though a sense of reverence or a feeling that what is experienced is holy or divine may be included.

Category V: Objectivity and Reality

This category has two interrelated elements: (1) insightful knowledge or illumination felt at an intuitive, non-rational level, gained by direct experience, and (2) the authoritativeness of the experience, or the certainty that such knowledge is truly real, in contrast to the feeling that the experience is a subjective delusion. These two elements are connected because the knowledge through experience of ultimate reality (in the sense of being able to "know" and "see" what is really real) carries its own sense of certainty. The experience of "ultimate" reality is an awareness of another dimension not the same as "ordinary" reality (the reality of usual, everyday consciousness), yet the knowledge of "ultimate" reality is quite real to the experiencer. Such insightful knowledge does not necessarily mean an increase in facts, but rather intuitive illumination. What becomes "known" (rather than only intellectually assented to) is intuitively felt to be authoritative, requires no proof at a rational level, and has an inward feeling of objective truth. The content of this knowledge can be divided into two main types: (a) insights into being and existence in general, and (b) insights into one's personal, finite self.

Category VI: Paradoxicality

Accurate descriptions and even rational interpretations of the mystical experience tend to be logically contradictory when strictly analyzed. For example, in the experience of internal unity there is a loss of all empirical content in an *empty* unity which is at the same time *full* and complete. This loss includes the loss of the sense of self and dissolution of individuality, yet something individual remains to experience the unity. The "I" both exists and does not exist. Another example is the separateness from, yet at the same time unity with, objects in the experience of external unity (essentially a paradoxical transcendence of space).

Category VII: Alleged Ineffability

In spite of attempts to tell or write about the mystical experience, mystics insist that words fail to describe it adequately or that the experience is beyond words. Perhaps the reason is an embarrassment with language because of the paradoxical nature of the essential phenomena.

Category VIII: Transiency

Transiency refers to duration and means the temporariness of the mystical experience in contrast to the relative permanence of the level of usual experience. There is a transient appearance of the special and unusual levels or dimensions of consciousness which are defined by our typology, with eventual disappearance and return to the more usual. The characteristic of transiency indicates that the mystical state of consciousness is not sustained indefinitely.

Category IX: Persisting Positive Changes in Attitude and/or Behavior

Because our typology is of a healthful, life-enhancing mysticism, this category describes positive, lasting effects which are the result of the experience. These changes are divided into four groups: (1) toward self, (2) toward others, (3) toward life, and (4) toward the mystical experience itself.

(1) Increased integration of personality is the basic inward change in the personal self. Undesirable traits may be faced in a way that enables them to be dealt with and finally reduced or eliminated. Issuing from personal integration, the sense of one's inner authority may be strengthened, and the vigor and dynamic quality of a person's life may be increased; creativity and greater achievement efficiency may be released; there may be an inner optimistic tone with consequent increase in feelings of happiness, joy and peace. (2) Changes in attitude and behavior toward others include more sensitivity, more tolerance, more real love, and more authenticity as a person by being more open and more one's true self with others. (3) Changes toward life in a positive direction include philosophy of life, sense of values, sense of meaning and purpose, vocational commitment, need for service to others, and new appreciation for life or the whole of creation. Life may seem richer. The sense of reverence may be increased, and more time may be spent in devotional life and meditation. (4)

Positive change toward the experience means that it is regarded as valuable and that what has been learned is thought to be useful. The experience is remembered as a high point, and an attempt is made to recapture the experience, or if possible, to gain new experiences as a source of growth and strength; mystical experiences of others are better appreciated and understood.

The purpose of the experiment in which psilocybin was administered in a religious context was to gather empirical data about the state of consciousness experienced. In a private chapel on Good Friday, twenty Christian theological students, ten of whom had been given psilocybin one and one-half hours earlier, listened over loud speakers to a two and one half hour religious service which was in actual progress in another part of the building, and which consisted of organ music, four solos, readings, prayers, and personal meditation. The assumption was made that for experiences most likely to be mystical, the atmosphere should be broadly comparable to that achieved by tribes who actually use natural psychedelic substances in religious ceremonies. The particular content and procedure of the ceremony had to be applicable (familiar and meaningful) to the participants. Attitude toward the experience, both before and during, was taken into serious consideration in the experimental design. Preparation was meant to maximize positive expectation, trust, confidence, and reduction of fear. Setting was planned to utilize this preparation through group support and rapport, friendship, an open and trusting atmosphere, and prior knowledge of the procedure of the experiment in order to eliminate, if possible, feelings of manipulation which might arise.

In the weeks before the experiment, each subject participated in five hours of various preparation and screening procedures which included psychological tests, medical history, physical examination, questionnaire evaluation of previous religious experience, intensive interview, and group interaction. The twenty subjects were graduate-student volunteers, all from a middle-class Protestant background and from one denominational seminary in the free-church tradition. None of them had ever taken psilocybin or related substances before this experiment. The volunteers were divided into five groups of four students each on the basis of compatibility and friendship. Two leaders who knew from past experience the positive and negative possibilities of the psilocybin reaction met with their groups to encourage trust, confidence, group support, and fear reduction. The method of reaction to the experience was emphasized (to relax and cooperate with, rather than to fight against, the effects of the drug). Throughout the preparation, an effort was made not to suggest the characteristics of the typology of mysticism. The leaders were not familiar with the typology which had been devised.

Double-blind technique was employed in the experiment so that neither the experimenter nor any of the participants (leaders or subjects) knew the specific contents of the capsules which were identical in appearance. Half of the subjects and one of the leaders in each group received 30 mg of psilocybin. Without prior knowledge of the effects, the remaining subjects and the other leader received 200 mg of nicotinic acid, a vitamin which causes transient feelings of warmth and tingling of the skin, in order to maximize suggestion for the control group.

Data were collected during the experiment and at various times up to six months afterwards. On the experimental day, tape recordings were made both of individual reactions immediately after the religious service and of the group discussions which followed. Each subject wrote an account of his experience as soon after the experiment as was convenient. Within a week all subjects had completed a 147-item questionnaire, designed to measure the various phenomena of the typology of mysticism on a qualitative numerical scale. The results of this questionnaire were used as the basis for a one and one half hour, tape-recorded interview which immediately followed. Sixth months later, each subject was interviewed again, after completion of a follow-up questionnaire in three parts with a similar scale. Part I was open-ended; the participant was asked to list any changes which he felt were a result of his Good Friday experience and to rate the degree of benefit or harm of each change. Part II (52 items) was a condensed and somewhat more explicit repetition of items from the post-drug questionnaire. Part III (93 items) was designed to measure both positive and negative attitudinal and behavioral changes which had lasted for six months and were due to the experience. The individual descriptive accounts and Part I of the follow-up questionnaire were content-analyzed with a qualitative, numerical scale by judges who were independent from the experiment and knew only that they were to analyze twenty accounts written by persons who had attended a religious service.

Prior to the experiment, the twenty subjects had been matched into ten pairs on the basis of data from the pre-drug questionnaires, interviews, and psychological tests. Past religious experience, religious background, and general psychological make-up were used for the pairings in that order of importance. The experiment was designed so that by random distribution one subject from each pair received psilocybin and one received the control substance, nicotinic acid. This division into an experimental and control group was for the purpose of statistical evaluation of the scores from each of the three methods of measurements which used a numerical scale: the post-drug questionnaire, the follow-up questionnaire, and the content analysis of the written accounts.

A summary of percentage scores and significance levels reached by the ten experimentals and ten controls for each category or subcategory of the typology of mysticism, is presented in Table 1.

The score from each of the three methods of measurement was calculated as the percentage of the maximum possible score if the top of the rating scale for each item had been scored. The percentages from each method of measurement were then averaged together. A comparison of the scores of the experimental and control subject in each pair was used to calculate the significance level of the differences observed by means of the non-parametric Sign Test. As can be seen from Table 1, for the combined scores from the three methods of measurement, *p* was less than .020 in all categories except deeply felt positive mood (love) and persisting positive changes in attitude and behavior toward the experience where *p* was still less than .055.

Table 1
Summary of percentage scores and significance levels reached by the experimental versus the control group for categories measuring the typology of mystical experience.

% of Maximum Possible	***Category Score for 10 Ss***		
	Exp	**Cont**	***p* <**
I. *Unity*	62	7	.001
A. Internal	70	8	.001
B. External	38	2	.008
II. *Transcendence of time and place*	84	6	.001
III. *Deeply felt positive mood*	57	23	.020
A. Joy, blessedness and peace	51	13	.020
B. Love	57	33	.055
IV. *Sacredness*	53	28	.020
V. *Objectivity and Reality*	63	18	.011
VI. *Paradoxicality*	61	13	.001
VII. *Alleged ineffability*	66	18	.001
VIII. *Transiency*	79	8	.001
IX. *Persisting positive changes in attitude and behavior*	51	8	.001
A. Toward self	57	3	.001
B. Toward others	40	20	.002
C. Toward life	54	6	.011
D. Toward the experience	57	31	.055

Although this evidence indicates that the experimentals as a group experienced, to a statistically significant degree, a higher score in each of the nine categories than did the controls, the degree of completeness or intensity must be examined.

In terms of our typology of mysticism, ideally the most "complete" mystical experience should have demonstrated the phenomena of all the categories in a maximal way. The evidence (particularly from the content analysis and also supported by impressions from the interviews) showed that such perfect completeness in all categories was not experienced by all the subjects in the experimental group. In the data the various categories and subcategories can be divided into three groups in regard to the degree of intensity or completeness as shown in Table 2.

Table 2
Relative completeness* of various categories in which there was a statistically significant difference between experimental and control groups

(a) Closest approximation to the most complete and intense expression.	(b) Almost, but not quite as complete or intense as (a).	(c) Least complete or intense, though still a definite difference from the control group.
Internal unity	External unity	Sense of sacredness
Transcendence of time and space	Objectivity and reality	Deeply felt positive mood (love)
Transiency	Alleged ineffability	Persisting positive changes in attitude and behavior toward others and the experience.
Paradoxicality	Deeply felt positive mood (joy, blessedness, and peace)	
Persisting positive changes in attitude and behavior toward self and life.		

* Based on qualitative score levels and agreement among the three methods of measurement.

Criteria were the percentage levels and the consistency among different methods of measurement. The closest approximation to a complete and intense degree of experience was found for the categories of internal unity, transcendence of time and space, transiency, paradoxicality, and persisting positive changes in attitude and behavior toward self and life. The evidence indicated that the second group had almost but not quite the same degree of completeness or intensity as the first group. The second group consisted of external unity, objectivity and reality, joy, and alleged ineffability. There was a relatively greater lack of completeness for sense of sacredness, love, and persisting positive changes in attitude and behavior toward others and toward the experience. Each of these last eight categories or subcategories was termed incomplete to a greater or less degree for the experimentals, but was definitely present to some extent when compared with the controls. When analyzed most rigorously and measured against all possible categories of the typology of mysticism, the experience of the experimental subjects was considered incomplete in this strictest sense. Usually such incompleteness was caused by results of the content analyses.

The control subjects did not experience many phenomena of the mystical typology, and even then only to a low degree of completeness. The phenomena for which the scores of the controls were closest to (although still always less than) the experimentals were: blessedness and peace, sense of sacredness, love, and persisting positive change in attitude and behavior toward others and toward the experience.

The meaningful religious setting of the experiment would have been expected to have encouraged a response of blessedness, peace, and sacredness. In the case of love and persisting changes toward others and toward the experience, observation by the controls of the profound experience of the experimentals and interaction between the two groups on an interpersonal level appeared, from both post-experimental interviews, to have been the main basis for the controls' experience of these phenomena.

The experience of the experimental subjects was certainly more like mystical experience than that of the controls who had the same expectation and suggestion from the preparation and setting. The most striking difference between the experimentals and controls was the ingestion of thirty mg of psilocybin which, it was concluded, was the facilitating agent responsible for the difference in phenomena experienced.

After an admittedly short follow-up period of only six months, life enhancing and life-enriching effects, similar to some of those claimed by mystics, were shown by the higher scores of the experimental subjects when compared to the controls. In addition, after four hours of follow-up interviews with each subject, the experimenter was left with the impression that the experience had made a profound impact (especially in terms of religious feeling and thinking) on the lives of eight out of ten of the subjects who had been given psilocybin. Although the psilocybin experience was unique and different from the "ordinary" reality of their everyday lives, these subjects felt that this experience had motivated them to appreciate more deeply the meaning of their lives; gain more depth and authenticity in ordinary living; and rethink their philosophies of life and values. The data did not suggest that any "ultimate" reality encountered had made "ordinary" reality no longer important or meaningful. The fact that the experience took place in the context of a worship service, whose symbols were familiar and meaningful to the participants, appeared to provide a useful framework within which to derive meaning and integration from the experience, both at the time and later.

The relationship and relative importance of psychological preparation, setting, and drug were important questions raised by our results. A meaningful religious preparation, expectation, and environment appeared to be conducive to positive drug experiences, although the precise qualitative and quantitative role of each factor was not determined. For example, everything possible was done to maximize suggestion, but suggestion alone cannot account for the results because of the different experience of the control group. The hypothesis that suggestibility was heightened by psilocybin could not be ruled out on the basis of our experiment. An effort was made to avoid suggesting the phenomena of the typology of mysticism, and the service itself made no such direct suggestion.

Implications for Therapeutic Use

The data presented above suggests that indeed the basic psychological characteristics of the mystical experience can be facilitated and studied by the use of psychedelic drugs. The most important therapeutic implication is suggested by the ninth category, persisting positive changes in attitude and behavior, which were measured after six months. Although normal subjects were used and the changes measured were not removal of symptoms, the direction of change was toward more integrated, self-actualizing attitudes and behavior in life. Although the mystical experience has been called by many names - psychedelic, conversion, transcendental, peak, or one of cosmic consciousness - this realm of human experience should not be rejected as outside the realm of serious scientific study if it can be shown that a practical benefit can result. This can be tested. Our data would indicate that such an overwhelming experience, in which a person existentially encounters basic values such as the meaning of his life (past, present, and future), deep and meaningful interpersonal relationships and insight into the possibility of personal behavior change, can be therapeutic if approached and worked with in a sensitive and adequate way.

First, what have we learned about the best way to facilitate the mystical experience out of the variety of forms which a psychedelic drug experience may take? Preparation would seem to be very important. Who the patient is must be considered. In a sense, his whole life has been part of his psychological preparation, but the nature of his expectations, fears, etc., at the time of his drug session, may radically determine the direction his reaction takes. (The more the patient can trust his doctor the better his chances for a beneficial experience.) The establishment of a firm and trustful therapeutic relationship is essential, as in any productive psychotherapy.

The therapist or person who will be present or easily available at all times during the drug session should carefully plan the procedure with the patient in advance. Special attention should be paid to the environment in which the drug is given and to the stimuli to be introduced during the session. Beautiful surroundings are in general beneficial, but the setting must be adapted to the individual patient. An orthodox religious setting, while helpful to deeply religious persons such as ministers or theological students, might detract from the most meaningful experience of someone else. Music which intuitively appeals to the individual can be helpful, in general, smooth, peaceful, and majestic music is best (Brahms' *Requiem*, or other classical music, especially with a chorus of human voices). Flowers, candlelight, and beautiful objects may also be used to set a general feeling-tone of peace and trust; confusion and unexpected stimuli definitely should be avoided.

The dosage level and route of administration also profoundly affect the kind of drug experience obtained. There are many interesting effects (such as visual changes and hallucinations) from psychedelic drugs even at low dosages, but the mystical type of experience appears to be best facilitated by the higher doses. Perhaps more of the drug is needed to make material available from the deeper levels of the unconscious. The very powerfulness of the experience helps patients, with proper preparation and encouragement, to go along more easily with the drug effects and not waste psychic energy fighting or resisting the drug. Certainly there is a dose-related effect in regard to the level of consciousness reached with sodium amytal interviews or general anesthesia. An adequate dose of LSD would be 4 mcg/kg; for psilocybin, .6 mg/kg; and for mescaline, 10 mg/kg. The speed of onset of action of the drug may influence the kind of experience, perhaps because of the effect of surprise with a sudden overwhelming of resistance. This is especially true of I.M. psilocybin which acts in a powerful manner within two minutes after injection. It is interesting that I.M. mescaline and LSD do not have this immediate kind of action. In the case of LSD, the I.M. route takes almost as long to act as the oral (about 30 minutes). The duration of action may be of importance; there is less time in the drug reaction with psilocybin (4-5 hours) than with LSD (8-10 hours) or mescaline (10-12 hours); this may be an advantage or disadvantage, depending on the time available. If the patient has a mystical experience, it is generally most beneficial for the work of integration to let the reaction run its course without interruption by barbiturates or chlorpromazine, which are used sometimes routinely to terminate the effect after a predetermined time. The positive mystical experience can generate an afterglow effect which can be very rewarding.

Secondly, what are the most effective ways in which to aid the therapeutic work of integration? Adequate time should be provided by the patient to work through the experience. The next day should be quiet, peaceful, and free from the duties and responsibilities of normal routine activities, so that the patient can think about and work on what was learned. The patient should be encouraged to put into words or pictures the significant parts of his experience.

Any therapist who wants to use psychedelic drugs should be trained under the supervision of those who are skilled in the administration of these drugs. If the therapist has not taken the drug himself, he should familiarize himself with the possible effects by talking to many patients who have had the experience and by sitting with and observing patients who are undergoing the treatment. This helps by making the therapist sensitive to the areas of content which may be brought into awareness by the drug experience. His own frame of reference will undoubtedly influence the interpretation and even the content of his patient's experiences through suggestion.

If the therapist is sensitive and familiar with the characteristics of the mystical experience, he can be of more help in making therapeutic use of the insights gained from such an experience. His emphasis should be on integration and application of the experience to everyday life. A danger can be that the patient may tend to view the experience as so much of another reality that it may seem a pleasant escape from his problems. The therapist can work against this possibility in the preparation before, in the support given during, and in the work of integration after the session.

If more than one patient has a session on the same day, even if the sessions are separate a group discussion and sharing after the drug effects are over serve to illuminate the meaning of the various experiences and to provide an effective means of group therapy; communication, closeness, and group solidarity are enhanced to a striking degree. Group therapy can supplement the individual therapy which is needed to help integrate the experience over a longer period of time.

Thirdly, what are the frequency and number of sessions needed when mystical experiences occur? It has been observed that the patients themselves are reluctant to repeat a mystical experience too soon; perhaps this is because of the characteristic of sacredness. The release of a large amount of unconscious material no doubt needs time to be adequately integrated. The hope is that relatively fewer large-dose drug sessions would be needed to accomplish the same result as the more frequent and numerous low-dose multiple sessions. By the very nature of the impact of mystical experience, more time would be needed between sessions for the work of integration. The possibility arises that such sessions might be most useful at selected points during regular therapy when progress was blocked, but certainly only after a strong relationship of trust had been established.

Discussion

These three questions - the best way to facilitate the mystical experience; the most effective means by which to aid the therapeutic work of integration; the optimal number and frequency of sessions - all can be tested experimentally. They are all facets of a much more basic question: can the mystical experience be therapeutic? Much research needs to be done in this area and perhaps the place to do it would be at a center where the best insights and trained personnel are available from psychiatry, clinical psychology and religion. An in-patient facility would be essential so that patients could be adequately prepared and then observed and helped afterwards as necessary. Screening could be done by medical history, psychiatric interview, and psychological testing; religious background and experience may also be an important variable and should not be ignored.

Theoretically there should be no reason why a patient could not be referred to such a specialized center for intermittent psychedelic drug sessions. The therapist might want to be present during the session but, if not, he could use the material obtained in his ongoing therapy with the patient. The therapist's attitude toward the treatment would play a crucial role not only in the patient's expectation and preparation for the treatment but also in the kind of experience obtained. Whether such an arrangement would work out satisfactorily could be tested experimentally.

Not all types of patients may do well if mystical experiences are facilitated through the use of the high-dose technique. For some, the small-dose, multiple-session method may be better. Research is needed to answer this question as well.

With such powerful agents, the possible dangers must never be forgotten. As with any potentially pleasant experience, psychological habituation is possible. The possible deleterious effects from continual use over a long period of time are not known. This consideration would argue in favor of fewer treatments of maximal effectiveness and impact. If the supply of these drugs is administrated only through psychiatrists trained in their use, the danger of habitual use is minimized. Pre-psychotic or borderline individuals with weak ego-structure may be disintegrated and become prolongedly psychotic if given these drugs; proper screening should eliminate such patients. Most psychotic episodes evoked by these drugs are temporary; the incidence and severity of such reactions can be reduced by proper preparation before and handling during a drug session.

Summary

Data were presented to show that psychedelic drug experience can be very similar to if not identical with the experiences described by mystics. A nine-category typology of mystical experience was defined and a double-blind controlled experiment was described in which normal subjects were given psilocybin in a supportive, religiously meaningful setting. The experiences of the experimental subjects were more like the mystical typology than those of the controls at a significance level well below expectation. The therapeutic implications of this kind of psychedelic drug experience were discussed in regard to the best way to facilitate mystical experience, the most effective means by which to aid the work of integration, and the optimal number and frequency of sessions. The challenging possibilities of future research in this area were suggested, and the possible dangers mentioned.

Polemics

Dr. Osmond: Dr. Pahnke, I want first to congratulate you upon your contribution. Then I want to make one very serious criticism and one minor criticism. The serious criticism is this: looking through the bibliography and seeing your Alma Mater, I see with great sorrow that the name of the greatest American psychologist who contributed most heavily to this field, and the man who introduced Freud to this country, has been omitted; and I do urge that this should be repaired. I don't think that a paper on this subject should appear, especially a good paper and a paper with such fascinating data, without William James's name being attached to it. That is, James would have delighted in this. He was at Harvard; I am certain he would have participated in this conference, and he would have been one of the first to do so. As you know, it was unfortunate that his weak stomach prevented him from enjoying peyote, and this was the only reason that he did not himself undertake this work; and I hope that you will repair this. Now, the next thing, regarding the idea of the one-shot experience: I think this is a mistake, although perhaps to some extent I may have been partly responsible for this. The actual evidence from the whole mystical literature, from which some of this is derived, was the fact that the idea was, as Aldous Huxley pointed out, that it is a free grace, as it were, for which you are then expected to do some work. You might say it is insight bought on the hire-purchase system, but you are expected to do something afterwards; and I'm sure that this has really been in everyone's mind. But I do hope that you will take my only serious criticism to heart, because I think it would be a great shame if James's name were not there.

Dr. Pahnke: I would agree one hundred percent with all of your comments. This work formed the basis for my Ph.D. thesis at Harvard, and in my thesis I give James full due. You probably agree no more strongly than I do with James, but I didn't want to include all my references to the mystical literature and to those scholars who have been interested in mysticism. I perhaps relied more heavily on Stace than on James.

Dr. Eisner: I think it's a beautiful job, and I'm particularly glad to see you break down the different categories, because it helps me; it helps resolve in my mind something that's bothered me. That's the invalid or pseudo-mystic or pseudo-cosmic experience. There are a couple of people who use LSD in Los Angeles, and when they first started using it, all of us in the area used to meet together for staff meetings. I would sit there with open mouth and hear how everyone and his patients were having the cosmic experience every time they had LSD. I couldn't figure it out. But their patients didn't change; this was the thing! And then they started telling me the way they would invoke these experiences by tricks and gimmicks. They might have them imagine they were in Belsen, and there were S.S. guards and their bodies were being destroyed by the flames. Then it would put them into a kind of cosmic state. I couldn't then understand why; but I see now, here, that this change in behavior is a very important variable to add to the mystic experience.

Dr. Baker: Could I ask about the terminology? I guess the people were given the material double-blind. But as the experience went on and as the follow-up goes on, it is no longer double-blind, is it? We don't want to make a mistake.

Dr. Pahnke: It was double-blind as far as is possible, but probably more blind from the standpoint of the subjects rather than the experimenter. I think we all know, and anyone who has worked with these drugs knows, that it is very difficult to keep fooling yourself once the drug reaction starts. The subjects were not ever told, though, and in the six-month follow-up, even at the one-week follow-up, many of them said, "I want to talk about what I think I had," and I said, "I don't want to hear about it," and kept it that way. But my own guesses all turned out to be right, and the subjects were all one hundred percent right as well.

Dr. Cohen: I'd like to hear again what instruction or statement you made to the subjects, for giving them the drug before the service.

Dr. Pahnke: These subjects were all males; they were between the ages of twenty-one and thirty-five; most of them were first-year theological students; we recruited them at one particular seminary. We had one group meeting initially with all the subjects and gave them the California Psychological Inventory and a questionnaire which measured past religious experience and background. These data were used to match the twenty subjects into ten matched pairs, but the subjects did not know about any of this. They were told only that they would have the chance to participate in an experience in which we were going to give them psilocybin, so they did know what drug they were going to get. They were also told that some of them would not get psilocybin. This was to decrease any sense of suspicion, distrust, and experimental manipulation which might have led to paranoid reactions, and also provide a more uniform expectation. I wasn't at all sure that it was even possible to facilitate the mystical experience, but I was doing everything I could to try to get it. Then there were two more meetings: one, an individual meeting with me when I took a medical history, gave each one a physical exam, and talked in more detail about his past religious experience; there was also a meeting in groups of four with their two guides, to give them a feeling of group solidarity for extra support. The main thing told to them at that time was what I have already indicated, about trusting, not being afraid, and surrendering, but the experience itself was not described.

Dr. Cohen: So the expectation was that they would receive psilocybin, a name with which they had some familiarity.

Dr. Pahnke: This was in 1962, and at that time there had not been the mass sensationalism and publicity that later emerged. Most of the subjects had not heard much about either LSD or psilocybin.

Dr. Cohen: Were there any adverse effects in the control group, great disappointment or whatever?

Dr. Pahnke: These were people who all wanted to have the psychedelic experience, so I told them at the time of recruiting that the control group, six months later, after the study was over, would be able to have the experience. This decreased the disappointment at the time of the experiment, but in the meantime there was much upheaval at Harvard, as I guess you all know, and I was not able to continue. Therefore, I could not offer the experience after the six-month follow-up. Then there was much disappointment; I was sorry about this.

Dr. Hoffer: I just wanted to ask Dr. Pahnke if he is ready to let me have his mystical experience questionnaire.

I'd like to use it on all my patients.

Dr. Pahnke: Yes, I'd be glad to. I have extra copies, and it's also in my thesis, which is on file at the Widener Library at Harvard University.

Dr. Savage: Do you think that this experience makes a better or worse minister? Do people give up the ministry? Or do they become more devoted, or do they stay about the same as they were before? Would you hazard a guess on that?

Dr. Pahnke: My guess is that the people who stay in the ministry would become better ministers if they have the drug reaction under conditions which allow for having a positive experience. Now, let me tell you what happened. I have done follow-up studies on these people to see what's happened to them in the intervening three years. At the time of the experiment, one boy from Georgia who came from a very fundamentalistic background was struggling with himself over whether he should go into the ministry, whether he should stick it out; he had just about decided to leave the seminary. After this experience he realized that he did have a deep interest in religion, and that he did want to go on and get his B.D. degree. This enthusiasm carried into the next fall, but at that time he again reconsidered and decided to drop out of the seminary. After one year he went back and got a master's degree at the same seminary and is now the assistant dean of a college in the South, doing religious counseling, and feels that he's much happier with this. So he feels that the experience helped him to get his bearings and to do what he really wanted. One person in the control group and two persons in the experimental group left the seminary before the end of training. This is not a statistically significant difference.

Dr. Ketchum: In view of the outstanding way in which this experiment was designed and carried out, and the seemingly highly useful nature of the results, I'd be interested now in hearing comments from the people who stated that controlled or double-blind experiments were, in general, not necessary or not useful.

Dr. Abramson: Psychotherapy was not involved.

Dr. Fremont-Smith: You're asking for comments from others. I regret that this must remain the only comment from others; we've got to go back to the discussion of this paper.

Dr. Unger: This is not an answer, but I think there has been a somewhat irrational bias that has reverberated throughout this meeting. But that's because most of the people here are involved in and pressured by clinical responsibilities and duties, whereas Dr. Pahnke was not. He was doing a piece of research, patient research that took time and opportunity. I don't think that there is a fundamental conflict that can't be resolved; I think, though, that many people who are involved in clinical work should be made aware of the necessity and the desirability of doing certain systematically controlled research, and not feel that we should come to the point where we consider it impossible to carry it out, because that's where much criticism of LSD research arises. Careful, controlled experiments are possible, but they involve the availability of enough time, proper facilities, and adequate training. Otherwise, such studies just cannot be done.

Dr. Pahnke: I might add that I did have full time to do this, and it took me a year and a half of solid effort to perform the experiment, analyze the results, and write it all up, because I had to do it all myself. I didn't have a grant, and it is time-consuming.

Dr. Rinkel: Professor Houston Smith of the Massachusetts Institute of Technology made a comment something like this: drugs appear able to induce religious experience. It is less evident that they can produce religious lives; but, although religion cannot be equated with religious experience, neither can it long survive its absence.

Dr. Pahnke: In my experiment, it was a very helpful thing that these students had a framework from which they came and to which they returned. They used their religious background as a way of interpreting the experience and utilizing the insights. I think the fact that they were going into religion professionally was a great help to them for integrating the experience in a useful way.

Dr. Ling: I'd like to ask the speaker to what extent this was a fair sample. You say it's a sample, you think, of the average religious student, but at the same time they volunteered for this. You do not think, perhaps, that volunteers are self-selective, and that's why they volunteered to answer their own problems? And, secondly, you stated that in order to get this experience you must produce a background that is symbolic and significant. Clearly a church is significant for a group of religious students, but would this carryover to, say, a law court, and how would it apply to an ordinary group of students?

Dr. Pahnke: This is the kind of experiment that would be useful to do in the future. Take a comparable group of people who are not professionally religious or even particularly interested in religion and give them the drug in a uniform setting. Another factor in the set could be controlled by comparing this group with another group of theological students or ministers. Then we could see whether both groups get the same experience. Now, the first point about the students being volunteers was true - they all volunteered. But remember, they were matched, and then randomly assigned to control group or experimental group, so I would assume that a fairly comparable population was assigned to the experimental and control group.

Dr. Ling: The only point I raised was that I have a counter-belief that volunteers volunteer for unconscious reasons.

Dr. Pahnke: Well, that may be so, but what I was trying to prove was whether it was possible to facilitate this experience or not, and in the control group these categories definitely were not present; in the experimental group they were. That was all I was trying to prove.

Dr. Dahlberg: Youmight have just answered my question, but I was wondering whether there were any of the people in the control group who did get the religious experience, perhaps through suggestion or influence by the people around them.

Dr. Pahnke: Suggestion was the same for both through preparation and during the experiment. Then, as I pointed out, when I analyzed the data with the three methods separately, the content analysis showed no significant difference in the sense of sacredness. You might expect this, because, in the control group, these people were ministers, too; they were in a Good Friday service; and they did have a higher score on sacredness than any other category for the control group, but they didn't have things, for example, like unity, or transcendence of time and space, or as intensive an experience of deeply felt mood as did the experimental group.

Dr. Dahlberg: I'm not talking about statistics now, I just wondered

Dr. Fremont-Smith: Did any of them have the experience, in the control group?

Dr. Pahnke: If you want to look at it that way, first you have to decide how many of the categories are to be considered necessary to the mystical experience.

Dr. Fremont-Smith: What's your definition of the experience, then? It's got to have the unity, and so forth?

Dr. Pahnke: Well, in order to decide which group had an experience which was more mystical, you must look at the statistics. You must compare one group against another, and you see whether by categories they have statistically-significant higher scores, one group or the other. Now if you want to break it down another way and consider subjects primarily, rather than categories, eight out of ten of the experimental subjects experienced at least seven out of nine of the categories. None of the control group, when each individual was compared to his matched partner, had a score which was higher; but some of the control group had scores which came up high enough to make the results not significantly different for some categories. Such statements really are not too significant unless you use groups of subjects compared statistically.

Dr. Fremont-Smith: Well, then, to the crude question, semi-crude question asked, whether any of the control group would be considered as having had -

Dr. Pahnke: Then you have to think about how high a score for each category you have to have in order to consider an experience mystical. If you look at Table 1, you will see, for each group, the percentage of the maximum possible for each score category. You can see what the control group score is and what the experimental group score is.

Dr. Fremont-Smith: Can we pull you away from the tables?

Dr. Pahnke: To take an individual case, there was one control subject who scored fairly high on sacredness and sense of peace and that...

Dr. Fremont-Smith: Did he think he'd had an unusual or...

Dr. Pahnke: ... And he himself, in his written account, said, "It was a very meaningful experience, but in the past I've certainly had one that was much more so."

Dr. Fox: The book by Maslow, called "The Psychology of Being," describes the transcendental experience as occurring without any drugs at all and, of course, he quotes James. It is what Freud called the oceanic experience. I have this quite often reported by my patients, particularly the artistic kind of person, and many of them use just the same phrases that you've been using. I know that, although such an experience may occur only once in a lifetime, it really is extremely important to that particular individual; he feels it with great conviction.

Dr. Pahnke: In a personal conversation with Professor Maslow, he said that he is, frankly, much more interested in these experiences at the lower level of the continuum. He said that spontaneously occurring peak mystical experiences certainly exist, but that they are so rare that he does not really find too many of them. He has studied mostly the ones that are still on the continuum, but at the lower end, like the woman who, during childbirth, has an ecstatic experience. I think I have demonstrated that, with psilocybin, it is possible to study the more rare, mystical experiences under controlled conditions.

Dr. Abramson: I would just like to return to the question of the double-blind procedure to amplify what I mentioned in connection with Dr. Unger's position. Major Ketchum, I think, thought that some of us here opposed controlled experiments, double-blind experiments, and the usual scientific procedures. I don't think that's true. I think what was meant by Dr. Fremont-Smith and myself and several others is that there are certain systems which are inherently incapable at present, because of poor methodology, of exploring with double-blind procedure. To reduce it to an absurd example, let's take one of Bridgman's problems: if you were to measure the distance from here to the moon by the velocity of light and by a yardstick, would the two agree? Well, you just can't do it, and I just don't think you can set up double-blind, controlled systems, if you're psychoanalyzing a patient. We just don't want to see poor methodology applied to systems where it cannot be applied. For example, I felt like attacking, just for the fun of it, the MMPI. And I've used that test for many years and published a few papers on it. When I started to use it, it was looked upon as a most disreputable test, because it was not projective. Now it suddenly has become so respectable that nearly everybody accepts it here. And I'm wondering why has this non-projective test suddenly assumed the cloak of respectability? Is it because it lends numerical elegance to physicians without clinical acumen? So, please bear with the clinician, as there are systems where you can't use the double-blind technique or the controls. Within-subject studies are certainly significant and cannot be avoided. Certainly in my work on normal test subjects I've done nothing but use single-blind and double-blind techniques, as well as everything possible, such as repeated placebo studies, to make certain I wasn't getting hysterical reactions. But in psychoanalyzing the patient, at present, unless one uses within-subject data, the data are inherently incapable of being tested.

Dr. Fremont-Smith: Could I add one phrase? And that is, it's not the question of applying poor scientific method to a difficult problem; it's a question of applying a good scientific method to a problem which is not appropriate to this method.

Dr. Ketchum: Well, I'd like to say that I'm glad Dr. Abramson and Dr. Fremont-Smith made these remarks. Actually, in a sense, I suppose I was playing devil's advocate because I do believe that double-blind procedures are either totally impossible or inappropriate to most of the problems under discussion. But I wanted this brought out because I think most of the people here feel the same way.

Dr. Fremont-Smith: Thank you very much. Now, Dr. Pahnke, would you like to close?

Dr. Pahnke: I feel that this area of psychology and religion is an area for serious scientific study, especially with these drugs. I feel that my experiment was only a first step. Who knows what the implications might be just for the one discipline that was mentioned - the training of ministers? I think this is an area where we need the best brains and insights and sensitivity not only from psychiatrists, but also from philosophers, theologians, and psychologists. I think that in doing further work, the various factors can be isolated and tested for their influence - for example, factors of set, setting, preparation, expectation and, last but not least, experimenter bias. I think these things can be done with carefully controlled studies; if they're not double-blind, at least they should have some kind of controlled comparison group, as Dr. Levine mentioned yesterday. I'd like to say that, in one sense, I agree with Dr. van Rhijn in his point that perhaps we should keep moving ahead to gain clinical experience with a drug which seems to show therapeutic promise in difficult cases, and not be stopped by the lack of double-blind studies; but on my trip to Europe last year, when I visited most of the centers where LSD is being given, I was struck by the lack of control groups of any kind in Europe. They do have control groups in the sense that a patient can be his own control, but you can never be sure that these patients might not have gotten better spontaneously. Now I think my paper has been an introduction to the paper to follow, because the work that has been going on at Spring Grove State Hospital is an effort to try to work with the psychedelic, mystical experience in alcoholics and utilize the positive implications of this experience.

Classic psychedelic use is associated with reduced psychological distress and suicidality in the United States adult population

Abstract

Mental health problems are endemic across the globe, and suicide, a strong corollary of poor mental health, is a leading cause of death. Classic psychedelic use may occasion lasting improvements in mental health, but the effects of classic psychedelic use on suicidality are unknown. We evaluated the relationships of classic psychedelic use with psychological distress and suicidality among over 190,000 USA adult respondents pooled from the last five available years of the National Survey on Drug Use and Health (2008-2012) while controlling for a range of covariates. Lifetime classic psychedelic use was associated with a significantly reduced odds of past month psychological distress (weighted odds ratio (OR)=0.81 (0.72-0.91)), past year suicidal thinking (weighted OR=0.86 (0.78-0.94)), past year suicidal planning (weighted OR=0.71 (0.54-0.94)), and past year suicide attempt (weighted OR=0.64 (0.46-0.89)), whereas lifetime illicit use of other drugs was largely associated with an increased likelihood of these outcomes. These findings indicate that classic psychedelics may hold promise in the prevention of suicide, supporting the view that classic psychedelics' most highly restricted legal status should be reconsidered to facilitate scientific study, and suggesting that more extensive clinical research with classic psychedelics is warranted.

Keywords: Psychedelic, hallucinogen, lysergic acid diethylamide, psilocybin, mescaline, mental health, suicide, prevention

Introduction

Almost half of a billion people worldwide suffer from mental health problems, at substantial cost to society (World Health Organization, 2001). Suicide is among the many deleterious consequences of poor mental health and accounts for approximately one million deaths across the globe annually (Hawton and van Heeringen, 2009). Despite advances in mental health treatment over the past 60 years, suicide rates have not significantly declined in much of the world during this time (Varnik, 2012), suggesting the need for more innovative and effective mental health treatments. In response to this trend the National Institute of Mental Health has called for research on novel interventions that address the mechanisms underlying suicidal phenomena (National Action Alliance for Suicide Prevention: Research Prioritization Task Force, 2014). Treatments involving classic psychedelics may represent one such approach.

Classic psychedelics can occasion mystical-type experiences and have been used in sacramental healing contexts across cultures since time immemorial (Johnson *et al.*, 2008; Nichols, 2004). Among the most prominent of these substances are dimethyltryptamine (DMT; widespread in the plant kingdom), the semi-synthetic lysergic acid diethylamide (LSD; derived from the ergot fungus), mescaline (the primary active constituent of peyote and other cacti), and psilocybin (the primary psychoactive constituent of *Psilocybe* and other mushroom genera), with primary effects caused by their action as agonists on serotonin 2A (5-HT_{2A}) brain receptors (Vollenweider and Kometer, 2010). Western science devoted significant attention to classic psychedelics from the 1950s through the early 1970s, and though a lack of modern methodological rigor complicates interpretation, results suggested that classic psychedelics might potentiate psychotherapeutic effectiveness (Johnson *et al.*, 2008; Nichols, 2004; Vollenweider and Kometer, 2010). To the dismay of responsible investigators, sensationalized media coverage of recreational classic psychedelic use in the 1960s led to the most severe legal restrictions, which all but eliminated the possibility of future study that might have yielded more conclusive findings. These legal restrictions were enacted in the absence of a compelling medical or scientific rationale, and contemporary analysis suggests that classic psychedelics are among the least harmful of misused drugs, with limited dependence potential (Nutt *et al.*, 2007, 2010).

The past three decades have witnessed a gradual return to research on classic psychedelics. Though limited in number, these studies indicate that classic psychedelics may warrant the attention they received five decades ago, not least in part because they appear to target a number of factors that modulate suicide risk. For instance, affective disturbance is one of the most prominent contributors to suicidality (Hawton and van Heeringen, 2009). Under carefully controlled conditions, a single administration of psilocybin can occasion profoundly meaningful experiences that bring about persisting elevations in mood among healthy, hallucinogen-naïve volunteers (Griffiths *et al.*, 2006, 2008, 2011). In a pilot trial among individuals with advanced-stage cancer a single dose of psilocybin was associated with long-term reductions in anxiety and depression (Grob *et al.*, 2011), and in a pilot trial among individuals with life-threatening diseases two administrations of LSD produced lasting reductions in anxiety (Gasser *et al.*, 2014; in press). Substance misuse also is robustly related to suicide risk (Borges *et al.*, 2000; Britton and Conner, 2010; Center for Substance Abuse Treatment, 2008; Hawton and van Heeringen, 2009; Wilcox *et al.*, 2004), and several lines of research suggest that classic psychedelics have anti-addictive effects (Bogenschutz and Pommy, 2012). For example, a recent meta-analysis of six randomized clinical trials of treatment for alcoholism conducted between 1966-1970 found that a single dose of LSD reduced the probability of alcohol misuse almost two-fold relative to comparison conditions (Krebs and Johansen, 2012). Furthermore, a single-arm trial of smoking cessation involving up to three administrations of psilocybin yielded abstinence rates of 80% at long-term follow-up, more than doubling abstinence rates typical of approved contemporary tobacco dependence interventions (Johnson *et al.*, 2014). Moreover, naturalistic hallucinogen use predicted a reduced likelihood of recidivism among more than 25,000 individuals under community corrections supervision with a history of substance involvement (Hendricks *et al.*, 2014). Additional prominent suicide risk factors include impulsive-aggressive personality characteristics and early traumatic life events (Hawton and van Heeringen, 2009). Psilocybin may occasion enduring improvements in inner peace, patience, good-natured humor/playfulness, interpersonal regard, anger, and compassion (Griffiths *et al*., 2006, 2011), and may facilitate processing of prior trauma by enhancing recall of autobiographical memories (Carhart-Harris *et al*., 2012a). Finally, classic psychedelics may boost spirituality (Bogenschutz and Pommy, 2012; Griffiths *et al*., 2011), which has been shown to protect against suicidality (Rasic *et al*., 2009, 2011; Weber and Pargament, 2014). Although sample sizes in recent medical administration studies have been limited, no serious adverse events were reported, consistent with historical data indicating that these substances can be administered safely in medical contexts by using appropriate safeguards (Johnson *et al*., 2008).

Neurobiological experiments echo clinical findings, adding further evidence to suggest that classic psychedelics may modify processes implicated in suicidality. Increased 5-HT$_{2A}$ receptor density in the prefrontal cortex is associated with suicide risk factors (e.g. major depression) and suicidal behavior, and may reflect compensatory up-regulation of 5-HT$_{2A}$ receptors stemming from dysfunctional serotonergic transmission (Bhagwagar *et al*., 2006; Carballo *et al*., 2008; Meyer *et al*., 2003; Shelton *et al*., 2008). Classic psychedelic use down-regulates 5-HT$_{2A}$ receptors in the prefrontal cortex which may, in turn, normalize limbic hyperactivity associated with affective disturbance (Baumeister *et al*., 2014, Kraehenmann *et al*., in press; Vollenweider and Kometer, 2010). Reduced neuroplasticity (i.e. expression of brain-derived neurotrophic factor) is also associated with affective disturbance and suicide, and classic psychedelic use may elicit neuroplastic adaptation via glutamatergic transmission (Baumeister *et al*., 2014; Bogenschutz and Pommy, 2012; Dwivedi, 2010; Dwivedi *et al*., 2003; Vollenweider and Kometer, 2010). Furthermore, the default mode network (DMN) is hyperactive and hyperconnected among those with affective disorders, a state that may underpin negative rumination and rigid pessimism characteristic of these conditions (Carhart-Harris *et al*., 2014; Whitfield-Gabrieli and Ford, 2012). Classic psychedelics may normalize the DMN, thereby reducing this cognitive fixedness (Carhart-Harris *et al*., 2012b; Carhart-Harris *et al*., 2014; Muthukumaraswamy *et al*., 2013; Roseman *et al*., 2014; Tagliazucchi *et al*., 2014). In support of this view, a single dose of psilocybin increased personality openness 14 months post-administration (MacLean *et al*., 2011). Some studies show that openness may protect against suicide in older adults, though findings are mixed (Segal *et al*., 2012). Finally, emerging evidence suggests that classic psychedelics might reduce markers of central nervous system inflammation that are implicated in a host of mental health conditions and suicidal behavior (Black and Miller, in press; Szabo *et al*., 2014).

Despite evidence suggesting safety and efficacy, the legal status of classic psychedelics has not changed since 1971. Classic psychedelics remain Schedule I substances (designated as having a high potential for abuse, no currently accepted medical use, and a lack of accepted safety under medical supervision), rendering clinical research with these drugs extremely difficult to conduct (Nutt *et al*., 2013). Consequently, an understanding of the impact of classic psychedelics on mental health and suicidality remains incomplete. Given the regulatory difficulty associated with administering classic psychedelics to humans, population-based survey studies represent one means for examining the relationships of classic psychedelic use with mental health and suicidality. What population-based survey studies sacrifice in internal validity afforded by experimental methodology, they gain in external validity provided by large samples, minimal inclusion and exclusion criteria, and assessment of subjects in real-world settings (Kelley *et al*., 2003). To our knowledge, only one prior investigation has evaluated the population-level associations of classic psychedelic use with mental health. Using data drawn from 2001-2004 of the National Survey on Drug Use and Health (NSDUH), Krebs and Johansen (2013) tested the relationships of lifetime classic psychedelic use with worst month of the past year psychological distress, past year mental health treatment use, and past year *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV; American Psychiatric Association, 1994) symptom indicators among over 130,000 USA adults. They found that lifetime classic psychedelic use was largely unassociated with these outcomes, though some findings indicated that lifetime classic psychedelic use was associated with a decreased likelihood of certain mental health indices (e.g. past year mental health treatment utilization). The purpose of the current study was to examine the relationships of lifetime classic psychedelic use with past month psychological distress and past year suicidality using data drawn from the last five available years of the NSDUH at the time of analysis (2008-2012). Considering multiple lines of research indicating that classic psychedelics may be protective with regard to mental health problems and suicidality, we hypothesized that lifetime classic psychedelic use would be associated with a decreased likelihood of past month psychological distress, past year suicidal thinking, past year suicidal planning, and past year suicide attempt.

Methods

The NSDUH survey of the Substance Abuse and Mental Health Services Administration of the United States Department of Health and Human Services is conducted annually to estimate the prevalence of substance use and mental illness in the general USA civilian non-institutionalized population using a complex, probability sampling design (United States Department of Health and Human Services, 2009, 2010, 2011, 2012, 2013). NSDUH interviewers met with individuals in their homes, who listened to prerecorded survey questions on headphones and provided responses via computer. Participants in the current study were adult (≥18 years old) respondents of the NSDUH survey pooled across years 2008-2012 with valid data on the primary independent variable (lifetime classic psychedelic use) and all covariates (see below). These cross-sectional data were pooled across years 2008-2012 because standardized assessment procedures introduced in 2008 yielded the same variables for analysis. Weighted interview response rates were approximately 75%. Detailed information on NSDUH methodology is available elsewhere (https://nsduhweb.rti.org/respweb/homepage.cfm). The NSDUH survey was approved by the institutional review board of the Research Triangle Institute and the current analyses were approved by the institutional review board of the University of Alabama at Birmingham.

Data analysis

A unique identifier was created for each unique NSDUH respondent from years 2008-2012 using the Cantor pairing function. Respondents reporting they had ever, even once, used DMT (code 616 from variables HALNEWA, HALNEWB, HALNEWC, HALNEWD, or HALNEWE=1), ayahuasca (a South American drink that contains DMT; code 6103 from variables HALNEWA, HALNEWB, HALNEWC, HALNEWD, or HALNEWE=1), LSD (variable LSDFLAG=1), mescaline (variable MESC2=1), peyote or San Pedro (cacti that contain mescaline; variable PEYOTE2=1 or code 6077 from variables HALNEWA, HALNEWB, HALNEWC, HALNEWD, or HALNEWE=1), or psilocybin (variable PSILCY2=1) were coded as positive for lifetime classic psychedelic use; those indicating that they had never used any of these substances were coded as negative. We considered coding individuals who responded in the affirmative to a query concerning use of DMT, alpha-methyltryptamine (AMT), and 5-methoxy-*N,N*-diisopropyltryptamine (5-MeO-DIPT) ("Have you ever, even once, used any of the following: DMT, also called dimethyltryptamine, AMT, also called alpha-methyltryptamine, or Foxy, also called 5-MeO-DIPT?"; variable TRYPTM=1) as lifetime classic psychedelic users, but since DMT use in particular could not be determined from this query, and because the classification of AMT and 5-MeO-DIPT as classic psychedelics is inconclusive, this query was not used to classify lifetime classic psychedelic users (post-hoc analyses determined that doing so contributed only 362 additional individuals to the group of lifetime classic psychedelic users and had no meaningful impact on the results). A single variable corresponding to lifetime classic psychedelic use (yes=1 or no=0) was the primary independent variable in analyses.

The primary outcome variables included past month psychological distress (variable SPDMON; yes=1 or no=0) as measured by the widely used and well-validated Kessler Psychological Distress Scale (K6; Kessler *et al*., 2002, 2010; Khan *et al*., 2014), past year suicidal thinking ("At any time in the past 12 months... did you seriously think about trying to kill yourself?"; variable MHSUITHK; yes=1 or no=0), past year suicidal planning ("During the past 12 months, did you make any plans to kill yourself?"; variable MHSUIPLN; yes=1 or no=0), and past year suicide attempt ("During the past 12 months, did you try to kill yourself?"; variable MHSUITRY; yes=1 or no=0). Multivariate logistic regression was used to test the associations between lifetime classic psychedelic use and the primary outcomes while controlling for the following covariates: age in years (18-25, 26-34, 35-49, 50-64, or 65 or older); gender (male or female); ethnoracial identity (non-Hispanic White, non-Hispanic African American, non-Hispanic Native American/Alaska Native, non-Hispanic Native Hawaiian/Pacific Islander, non-Hispanic Asian, non-Hispanic more than one race, or Hispanic); educational attainment (5th grade or less, 6th grade, 7th grade, 8th grade, 9th grade, 10th grade, 11th grade, 12th grade, freshman college year, sophomore or junior college year, or senior college year or more); annual household income (less than $20,000, $20,000-$49,999, $50,000-$74,999, or $75,000 or more); marital status (married, divorced/separated, widowed, or never married); self-reported engagement in risky behavior ("How often do you like to test yourself by doing something a little risky?"; never, seldom, sometimes, or always) and lifetime illicit use of cocaine, other stimulants, sedatives, tranquilizers, heroin, pain relievers, marijuana, 3,4-methylenedioxymethamphetamine (MDMA)/ecstasy, phencyclidine (PCP), and inhalants (each aforementioned drug category coded as separate covariates). All analyses were conducted in SAS version 9.3 using PROC

SURVEYLOGISTIC and accounted for the complex study design variables and sampling weights as recommended by the NSDUH.

Results

Of the 191,382 respondents, 27,235 reported lifetime classic psychedelic use (13.6% weighted). Of these, 391 reported lifetime DMT use (0.1% weighted), 26 reported lifetime ayahuasca use (0.008% weighted), 18,152 reported lifetime LSD use (10.2% weighted), 4687 reported lifetime mescaline use (3.5% weighted), 3540 reported lifetime peyote or San Pedro use (2.4% weighted), and 20,274 reported lifetime psilocybin use (8.9% weighted). In addition, 12,657 of the respondents reported past month psychological distress (4.8% weighted), 10,445 reported past year suicidal thinking (3.8% weighted), 3157 reported past year suicidal planning (1.1% weighted), and 1716 reported past year suicide attempt (0.5% weighted).

Table 1. Characteristics of lifetime classic psychedelic users versus non-lifetime classic psychedelic users.

Feature	Lifetime classic psychedelic users Weighted %	Non-lifetime classic psychedelic users Weighted %	*p* value
Age, years			<0.0001
18-25	13.6	14.9	
26-34	21.3	14.9	
35-49	33.7	26.3

Lifetime marijuana use	97.7	36.2	<0.0001
Lifetime MDMA/ecstasy use	33.0	2.1	<0.0001
Lifetime PCP use	18.0	0.4	<0.0001
Lifetime inhalant use	39.5	3.8	<0.0001

All percentages were rounded to the nearest 0.1%. Rao-Scott chi-square tests were used to examine the characteristics of lifetime classic psychedelic users versus nonlifetime classic psychedelic users. MDMA: 3,4-methylenedioxymethamphetamine; PCP: phencyclidine.

Table 1 displays the characteristics of lifetime classic psychedelic users versus non-lifetime classic psychedelic users. Lifetime classic psychedelic use was concentrated among 26-64 year olds and rare among those aged 65 years and older. Furthermore, lifetime classic psychedelic use was more common among men, non-Hispanic Whites and Native Americans/Alaska Natives, those with greater educational attainment and income, individuals who were divorced/separated or who had never been married, those with greater self-reported engagement in risky behavior, and those who reported lifetime illicit use of each of the other substances. Among lifetime classic psychedelic users, only 240 (0.9% weighted) reported never having used any other illicit substance whereas among non-lifetime classic psychedelic users, 85,601 (58.2% weighted) reported never having used any other illicit drug. Figures 1-4 show the results of multivariate logistic regression models predicting past month psychological distress, past year suicidal thinking, past year suicidal planning, and past year suicide attempt. As shown in these figures, lifetime classic psychedelic use was associated with a decreased likelihood of past month psychological distress (weighted OR=0.81 (0.72-0.91), p=0.0002), past year suicidal thinking (weighted OR=0.86 (0.78-0.94), p=0.001), past year suicidal planning (weighted OR=0.71 (0.54-0.94), p=0.01), and past year suicide attempt (weighted OR=0.64 (0.46-0.89), p=0.008). Conversely, lifetime illicit use of other substances was either not related with or associated with an increased odds of these outcomes, with odds ratios (ORs) for all relationships exceeding 1.0 except lifetime PCP use and past month psychological distress, and lifetime MDMA/ecstasy use and past year suicidal thinking, past year suicidal planning, and past year suicide attempt (no OR significantly different than 1.0).

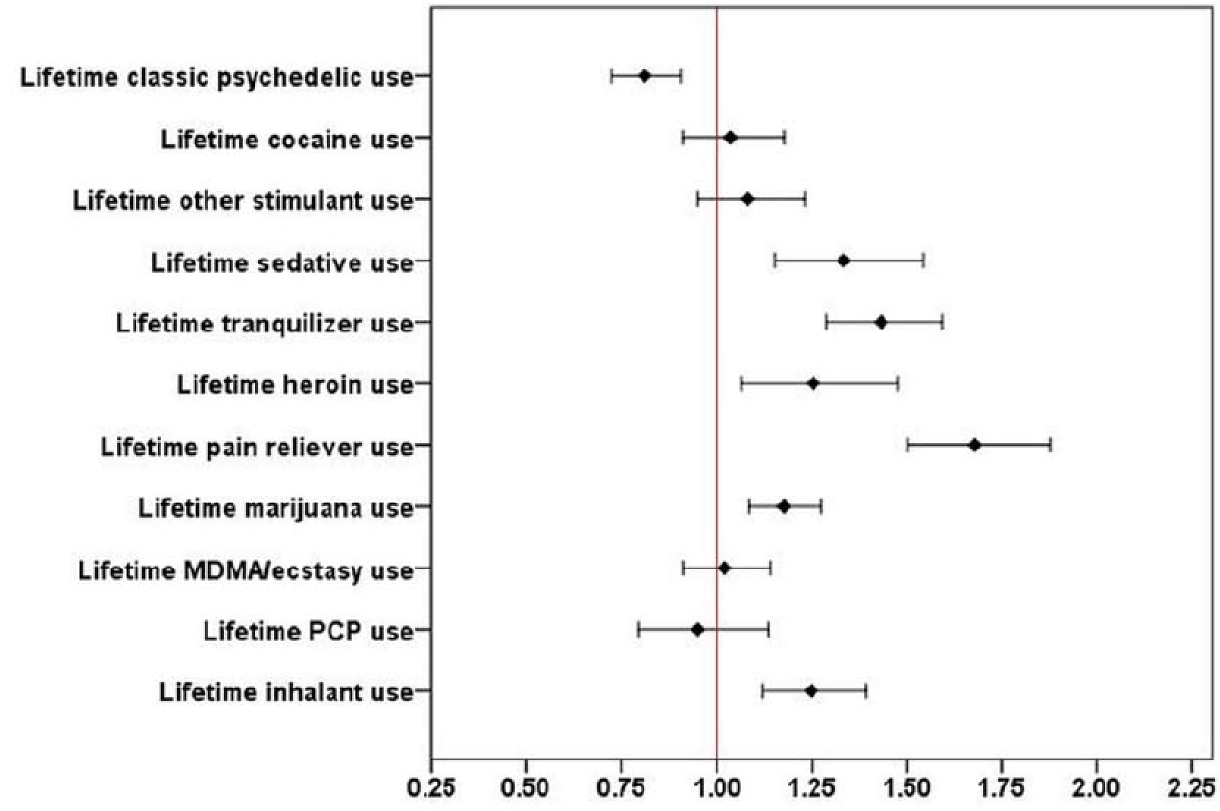

Figure 1. Result of multivariate logistic regression model predicting past month psychological distress. Diamonds are weighted odds ratio point estimates and error bars are 95% confidence intervals. Associations of demographic variables and self-reported engagement in risky behavior with psychological distress are not presented. *n*=191,369 due to missing data on the dependent variable. MDMA: 3, 4-methylenedioxymethamphetamine; PCP: phencyclidine.

Discussion

The objective of the current study was to evaluate the associations of classic psychedelic use with psychological distress and suicidality in a large sample generalizable to the USA adult population. Consistent with hypotheses, lifetime classic psychedelic use was associated with a 19% reduced likelihood of past month psychological distress, a 14% reduced likelihood of past year suicidal thinking, a 29% reduced likelihood of past year suicidal planning, and a 36% reduced likelihood of past year suicide attempt. These findings comport with the accumulating literature indicating that classic psychedelics may remediate a number of risk factors associated with suicide. Indeed, if the current results reflect a direct causal chain between classic psychedelic use and decreased suicidality, the mechanisms described in the introduction may have explanatory value. By contrast, lifetime illicit use of all other substances was by and large associated with an increased likelihood of psychological distress and suicidality at or above the trend level. These results align with data indicating that non-psychedelic substance use is a suicide risk factor (Borges *et al*., 2000; Britton and Conner, 2010; Center for Substance Abuse Treatment, 2008; Hawton and van Heeringen, 2009; Wilcox *et al*., 2004).

An obvious limitation of the current research is its reliance on self-report. Biases in responding may have obscured the true relationships of classic psychedelic use with psychological distress and suicidality. Also, analyses were restricted to the available data, which precluded testing more nuanced associations (e.g. dose-response relationships). Furthermore, as with any cross-sectional study, the associations reported here may not necessarily indicate causation. Population survey studies cannot control for all possible sources of confounding and therefore we cannot rule out that a shared underlying factor may have contributed to both classic psychedelic use and decreased psychological distress and suicidality. Psychedelic drug users commonly report autognostic (Móró *et al*., 2011), "mind expansion," spiritual, and curiosity motives for such use (Lyvers and Meester, 2012). Although these interests may be lasting effects of classic psychedelic drug use, they may also represent predrug characteristics among classic psychedelic users that might protect against suicide as well (e.g. openness, curiosity, and spiritual tendencies; Carhart-Harris *et al*., 2014; Kashdan *et al*., 2004; Rasic *et al*., 2009, 2011; Weber and Pargament, 2014). Lerner and Lyvers (2006) found that classic psychedelic users reported less materialistic values and greater mysticism, spirituality, and concern for others than non-classic psychedelic drug users, and speculated that both predrug factors and classic psychedelic drug effects contributed to group differences. This too may be the case with regard to the present findings. However, as classic psychedelic use was associated with self-reported engagement in risky behavior and illicit substance use, some who use classic psychedelics may also have a premorbid liability for suicidality. The picture is undoubtedly complex. Nevertheless, future research should attempt to delineate longitudinal predictors of classic psychedelic use that also relate to mental health and suicidal behavior.

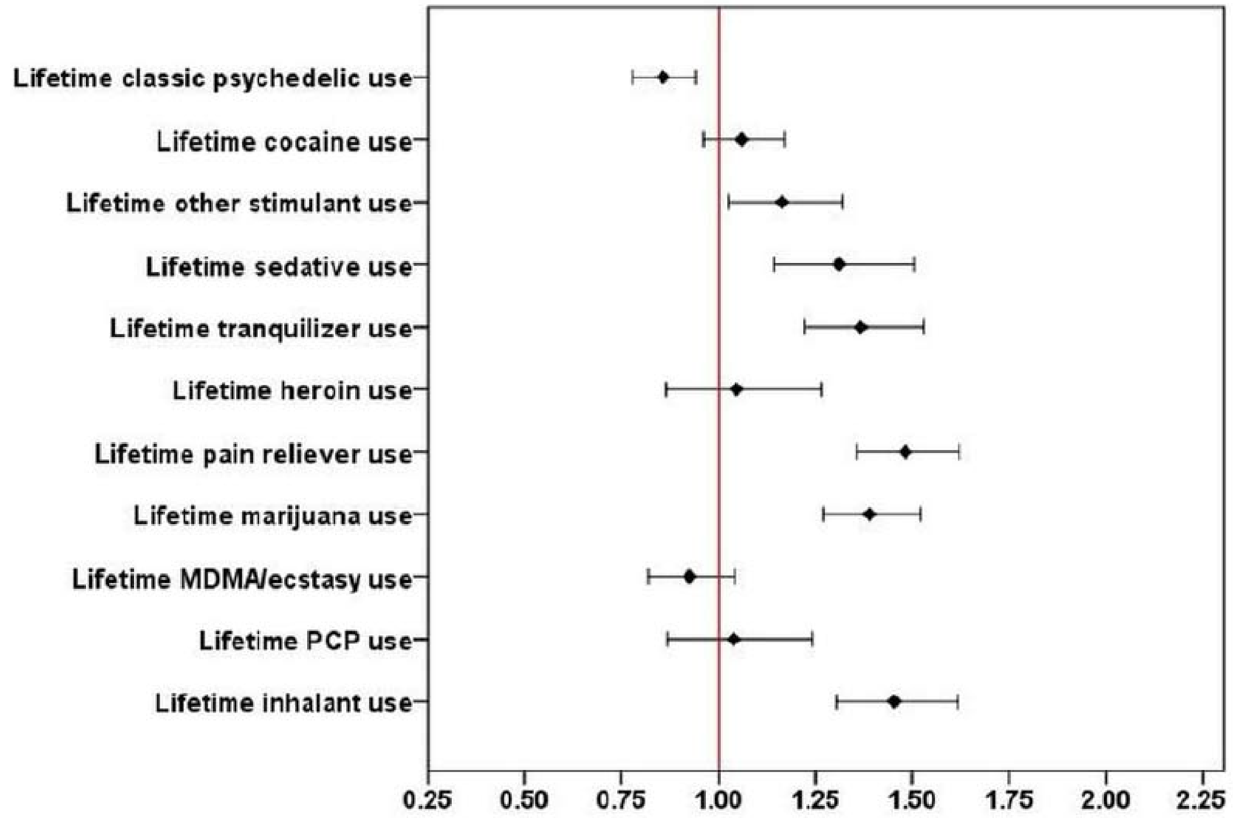

Figure 2. Result of multivariate logistic regression model predicting past year suicidal thinking. Diamonds are weighted odds ratio point estimates and error bars are 95% confidence intervals. Associations of demographic variables and self-reported engagement in risky behavior with suicidal thinking are not presented. *n*=190,728 due to missing data on the dependent variable. MDMA: 3, 4-methylenedioxymethamphetamine; PCP: phencyclidine.

We also cannot rule out the possibility that classic psychedelic use may have caused harm at the individual level. Indeed, classic psychedelic use may exacerbate schizophrenia or other psychotic disorders, can be dangerous in hazardous physical environments, and can sometimes elicit feelings of anxiety, fear, panic, and paranoia (Johnson *et al.*, 2008). Nevertheless, the associations reported here suggest that if individual-level harms occurred, they failed to obscure the apparent protective effect of classic psychedelic use on psychological distress and suicidality at the population level. Considering that carefully controlled conditions are ideal in the administration of classic psychedelics (Johnson *et al.*, 2008), it is noteworthy that naturalistic classic psychedelic use demonstrated evidence of benefit. Not only could classic psychedelic users have used in suboptimal settings, they could have ingested substances of unknown purity and/or at sub- or supratherapeutic doses. If the results do reflect salubrious effects of classic psychedelic use, these may very well be potentiated in specialized treatment settings designed to maximize safety and efficacy (Johnson *et al.*, 2008).

Given the grave and chronic nature of suicide (Hawton and van Heeringen, 2009; Varnik, 2012) and the call for research on innovative treatments that target suicide pathogenisis (National Action Alliance for Suicide Prevention: Research Prioritization Task Force, 2014), the current findings set the stage for more extensive clinical research with classic psychedelics. Despite millennia of use in sacred healing rituals, and accruing scientific evidence suggesting safety and efficacy when administered in clinical settings with appropriate safeguards (Johnson *et al.*, 2008), classic psychedelics remain Schedule I substances. Accordingly, evaluating the clinical application of classic psychedelics remains an arduous challenge secondary to regulatory hurdles and scarce funding, among other obstacles (Nutt *et al.*, 2013). The present results reinforce the perspective that the designation of these substances should be reconsidered to allow further scientific inquiry. Regardless, priorities for future investigation include evaluating the efficacy of classic psychedelics in treating suicidality as well as pathologies associated with increased suicide risk including affective disturbance, substance misuse, dysfunction marked by impulsive-aggressive personality traits, trauma sequelae, and neurocognitive deficits. Mediators of classic psychedelics' effects should be carefully evaluated so as to better understand their mechanisms of action. Elucidating such mechanisms is critical to optimizing the benefits of classic psychedelics and their concomitant psychotherapeutic components.

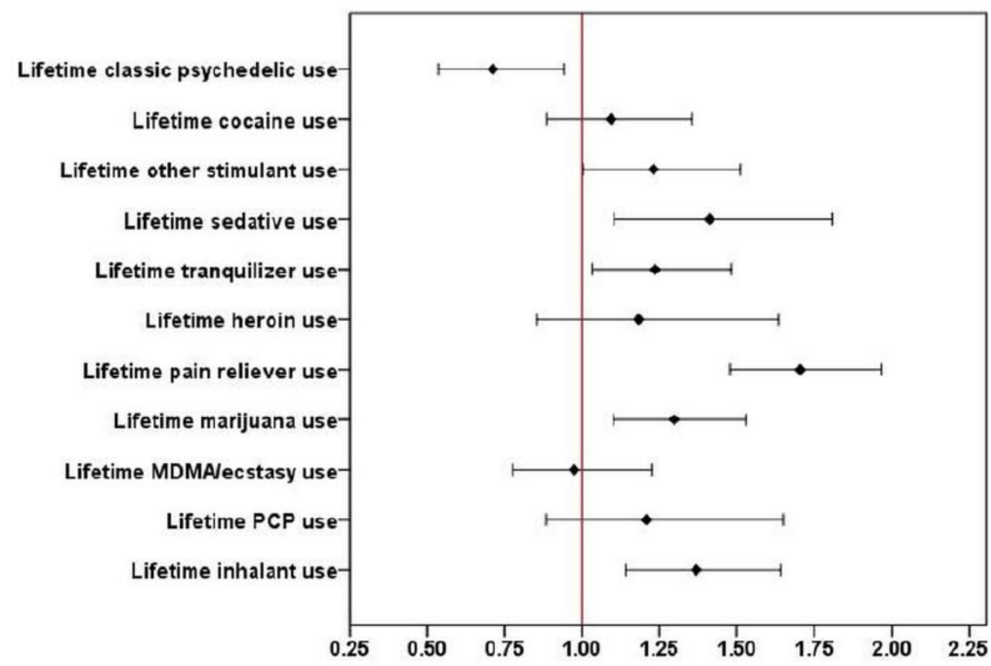

Figure 3. Result of multivariate logistic regression model predicting past year suicidal planning. Diamonds are weighted odds ratio point estimates and error bars are 95% confidence intervals. Associations of demographic variables and self-reported engagement in risky behavior with suicidal planning are not presented. *n*=190,713 due to missing data on the dependent variable. MDMA: 3,4-methylenedioxymethamphetamine; PCP: phencyclidine.

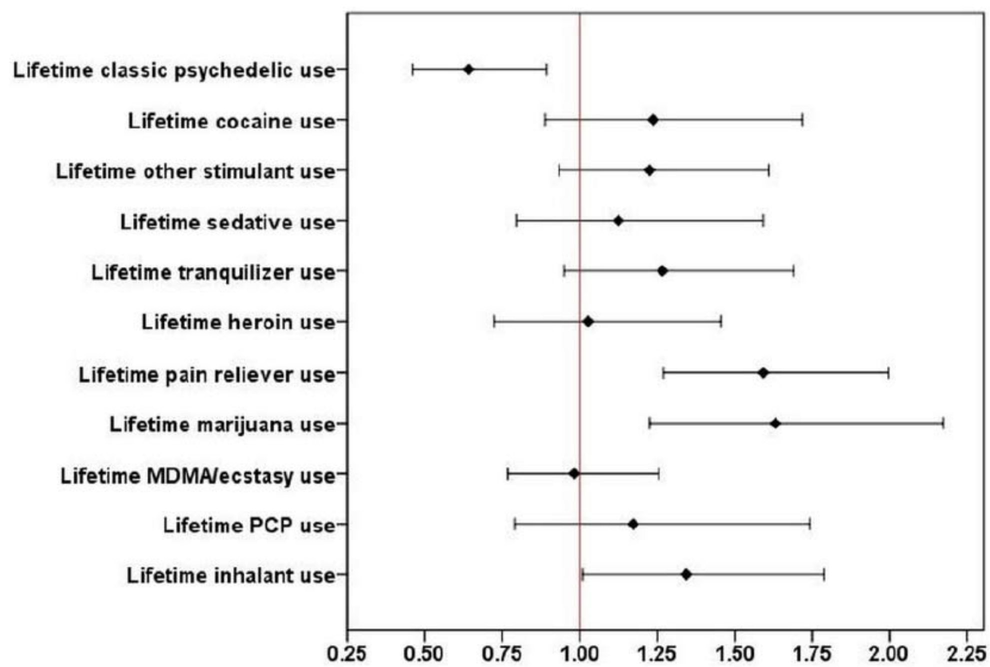

Figure 4. Result of multivariate logistic regression model predicting past year suicide attempt. Diamonds are weighted odds ratio point estimates and error bars are 95% confidence intervals. Associations of demographic variables and self-reported engagement in risky behavior with suicide attempt are not presented. *n*=190,709 due to missing data on the dependent variable. MDMA: 3,4-methylenedioxymethamphetamine; PCP: phencyclidine.

Conclusion

Classic psychedelics carry a contentious recent history and barriers to their clinical evaluation remain. Growing evidence including the present research suggests that classic psychedelics may have the potential to alleviate human suffering associated with mental illness. Further rigorous research is warranted to better understand these substances, with the ultimate goal of taking full advantage of their latent therapeutic capacity.

Abstract

A recent large population study of 130,000 adults in the United States failed to find evidence for a link between psychedelic use (lysergic acid diethylamide, psilocybin or mescaline) and mental health problems. Using a new data set consisting of 135,095 randomly selected United States adults, including 19,299 psychedelic users, we examine the associations between psychedelic use and mental health. After adjusting for sociodemographics, other drug use and childhood depression, we found no significant associations between lifetime use of psychedelics and increased likelihood of past year serious psychological distress, mental health treatment, suicidal thoughts, suicidal plans and suicide attempt, depression and anxiety. We failed to find evidence that psychedelic use is an independent risk factor for mental health problems. Psychedelics are not known to harm the brain or other body organs or to cause addiction or compulsive use; serious adverse events involving psychedelics are extremely rare. Overall, it is difficult to see how prohibition of psychedelics can be justified as a public health measure.

Keywords: Psychedelic, hallucinogen, epidemiology, public health, suicide

Introduction

The classical psychedelics lysergic acid diethylamide (LSD), psilocybin (magic mushrooms) and mescaline (peyote and other cacti) have their primary mechanism of action at the serotonin 2A (5-HT_{2A}) receptor, elicit similar, often indistinguishable effects and show cross-tolerance (Bonson, 2012). Over 30 million adults in the United States (US) have tried psychedelics (approximately one in six adults aged 21-64 years) (Krebs and Johansen, 2013a).

Psychedelics are not known to harm the brain or other body organs or to cause addiction or compulsive use (Halberstadt, 2015; Bonson, 2012). Psychedelics are well known for inducing profound effects on the mind, which sometimes include confusion and emotional turmoil (McWilliams and Tuttle, 1973). Both the European Monitoring Center for Drugs and Drug Addiction (EMCDDA) and the health authorities in the Netherlands, where hundreds of thousands of servings of psilocybin mushrooms are legally sold in shops each year, report that serious injuries related to psychedelics are extremely rare (EMCDDA, 2011; CAM, 2007). Furthermore, Dutch police report that legal sale of psilocybin mushrooms has not led to public order problems (van Amsterdam *et al.*, 2011). Approximately 0.005% of emergency department visits in the US involve LSD or psilocybin (US Department of Health and Human Services, Substance Abuse and Mental Health Services Administration, Center for Behavioral Health Statistics and Quality 2013; Centers for Disease Control and Prevention (CDC), 2014). Drug abuse experts consistently rank LSD and/or psilocybin mushrooms as much less harmful to the individual user and to society compared to alcohol and other controlled substances (Nutt *et al.*, 2007, 2010; Taylor *et al.*, 2012; van Amsterdam *et al.*, 2010). Controlled studies have not linked either clinical administration or regular use of psychedelics in religious ceremonies to lasting health problems (see Krebs and Johansen, 2013b).

Psychedelics often elicit deeply personally and spiritually meaningful experiences and sustained beneficial effects (Carhart-Harris and Nutt, 2010; Griffiths *et al.*, 2008, 2011; Morgan *et al.*, 2010). Common reasons for using psychedelics include mystical experiences and personal development (Hallock *et al.*, 2005). Indeed, in many countries, including the US, select groups have protection from prosecution on grounds of freedom of belief or religion. People have used psychedelics for at least 5700 years (Bruhn *et al.*, 2002), pre-dating the major organized religions. Modern antipsychedelic legislation began 100 years ago when members of rival religious groups campaigned against Native American peyote use, calling peyote addictive and an 'insidious evil' that causes users to 'withdraw from the churches and become "peyote worshipers"' (Newberne and Burke, 1922). Eventually, concerned scientists defended peyote users, using evidence-based reasoning and human rights arguments (Collier, 1952; La Barre *et al.*, 1951; Le Farge, 1960); this led to legal exemptions for specific groups. However, laws and cultural biases against peyote remained in place and were later extended to include other psychedelics. Concerns have been raised that the ban on use of psychedelics is a violation of the human rights to belief and spiritual practice, full development of the personality, and free time and play (United Nations General Assembly, 1948; Walsh, 2014).

There is increasing interest in the therapeutic use of psychedelics, especially for alcoholism (Krebs and Johansen, 2012), smoking cessation (Johnson *et al.*, 2014), depression and other mental health problems (Baumeister *et al.*, 2014; Bogenschutz, 2013; Hendricks *et al.*, 2014). David Nutt and colleagues have explained how national and international regulations have impeded scientific research and medical treatment development with psychedelics and other highly controlled 'Schedule I' substances (Nutt *et al.*, 2013). Prohibition has also obviously had negative consequences for the millions of individuals who find it worthwhile to use these substances in various cultural settings outside of the clinic.

Our previous population study failed to find evidence for a link between psychedelic use (lifetime use of LSD, psilocybin, mescaline, or peyote, past year use of LSD) and past year serious psychological distress, receiving or needing mental health treatment, or symptoms of eight psychiatric diagnoses, including major depression, anxiety disorders, mania and psychosis, or visual hallucinations (Krebs and Johansen, 2013b). Here, using a new large data set, which included data on suicidal thoughts and suicide attempt, we again examine the associations between the use of psychedelics and mental health.

Materials and methods

Source, population and data

The annual National Survey on Drug Use and Health (NSDUH) collects data on substance use and mental health from a random sample representative of the US civilian non-institutionalized population (http://oas.samhsa.gov/nsduh.htm). We pooled data from respondents aged 18 years and over from survey years 2008-2011. Half of year 2008, earlier survey years and younger respondents were not pooled due to questionnaire differences (including no questions on suicidal behavior). The response rate was 78%. In addition, approximately 10% of participants were excluded from the public use data file, either because of excessive missing data on drug use or because they were excluded at random in order to increase anonymity. The sample consisted of 135,095 respondents, of whom 19,299 (13.6% weighted) reported lifetime use of a psychedelic substance. Our previous study examined NSDUH years 2001-2004 (Krebs and Johansen, 2013b).

Use of psychedelics

We counted participants as having any lifetime psychedelic use if they reported use of LSD, psilocybin, mescaline or peyote. LSD, psilocybin and mescaline are all classical serotonergic psychedelics with main mechanism of action at the 5-HT$_{2A}$ receptor (Halberstadt, 2015). We combined mescaline and peyote (mescaline-containing cactus) use into one variable but also examined peyote use separately. Data on past year use was available only for LSD.

Mental health indicators

We examined 11 self-reported indicators of past year mental health problems. Past year mental health indicators also used in our previous study (Krebs and Johansen, 2013b) were serious psychological distress during the worst month of the past year, assessed with the K6 scale (Kessler *et al.*, 2003a), mental health treatment, including treatment for substance disorders (inpatient, outpatient, psychiatric medication prescription, felt a need for but did not receive mental health treatment). The remaining mental health indicators from our previous study, such as psychosis symptoms, were not available in this data set. Past year mental health indicators new to this study were suicide thoughts, suicide plan, suicide attempt, symptoms of major depressive episode (assessed with a questionnaire adapted from the National Comorbity Survey (Kessler *et al.*, 2003b), which was different from the depression questionnaire in our previous study), physician diagnosis of depression, and physician diagnosis of an anxiety disorder.

The K6 scale provides a valid assessment of general psychological distress during the worst month of the past year. It covers types of psychological distress that are common to a broad range of psychiatric disorders and has strong accuracy in discriminating between people with and without one or more diagnoses from the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (American Psychiatric Association, 1994; Kessler *et al.*, 2010).

Control variables

Control variables consisted of a variety of sociodemographic, psychological and drug use variables (Figure 1, Tables 1 and 2). The control variables were selected on the basis of associations with mental health in previous research, and were the same as those used in our previous study, with two differences: depressive episode before age 18 was now available to be included as a control variable in this study, and lifetime exposure to an extremely stressful event was not available to be included.

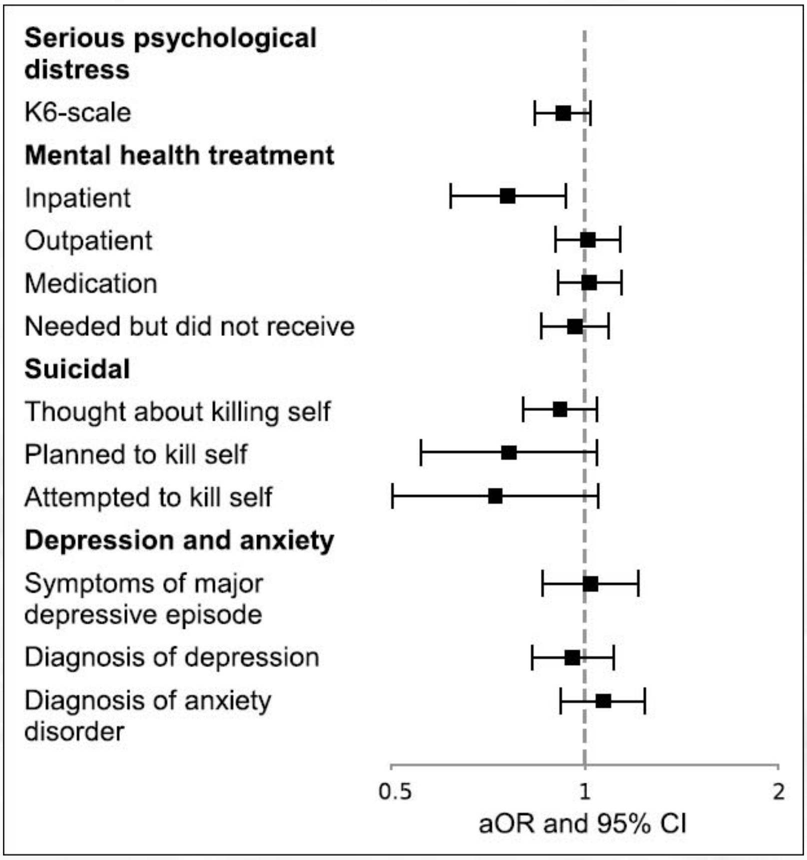

Figure 1. Association between psychedelic use and mental health. aOR: adjusted odds ratio. Values less than 1.0 indicate lower likelihood among people with lifetime psychedelic use, adjusted for age (11 categories, treated as a continuous variable), gender (male, female), race/ethnicity (white, Hispanic, black, Asian, Native American, Native Hawaiian or Pacific Islander, more than one), household income (less than US$20,000, US$20,000-49,999, US$50,000-74,999, US$75,000 or more), education (not high school graduate, high school graduate, some college, college graduate), marital status (unmarried, married), likes to test self by doing risky things (never, seldom, sometimes, always), depressive episode before age 18 years (no, yes), and 10 types of lifetime drug use (cannabis/marijuana, opiates, cocaine, sedatives/tranquilizers, stimulants, MDMA/ecstasy, inhaled anesthetics, amyl nitrates, other inhalants, phencyclidine); CI: confidence interval.

Participants with missing data were excluded; including participants with missing values had no effect on statistical significance. All calculations accounted for the NSDUH weighting variables and complex sample design. We used SPSS/PASW Statistics (version 18.0.3).

The control variables were age at interview (11 categories, treated as a continuous variable), gender (male, female), race/ethnicity (white, Hispanic, black, Asian, Native American, Native Hawaiian or Pacific Islander, more than one), household income (less than US$20,000, US$20,000-49,999, US$50,000-74,999, US$75,000 or more), education (not high school graduate, high school graduate, some college, college graduate), marital status (unmarried, married), likes to test self by doing risky things (never, seldom, sometimes, always), depressive episode before age 18 years (no, yes), and 10 types of lifetime drug use (cannabis/ marijuana, opiates, cocaine, sedatives/tranquilizers, stimulants, MDMA/ecstasy, inhaled anesthetics, amyl nitrates, other inhalants, phencyclidine). Additionally, in the analyses of past year use of LSD we also included as control variables past year use of the other drugs listed above, but with only one variable for any past year inhalant use because data on specific inhalants were not available.

Data analysis

We used multivariate logistic regression to calculate adjusted odds ratio (aOR) associations between mental health variables and lifetime use of any psychedelics, lifetime use of the specific psychedelics (LSD, psilocybin, mescaline/peyote, peyote) and past year use of LSD. We also calculated associations between mental health and use of any psychedelics in subgroups stratified on sex, age (18-25 years, 26 or older), past year illicit drug use and depressive episode before age 18.

All unstratified analyses had 25 or more events per control variable, and all stratified analyses had eight or more events per control variable (Vittinghoff and McCulloch, 2007). For all control variables the variance inflation factors were under 2.5, indicating little multi-collinearity.

Table 1. Sociodemographic and psychological variables

	Ever used psychedelics		Never used psychedelics		% used psychedelics

Results

Psychedelic users were more likely than non-users to report a depressive episode before age 18. They were also more likely to be younger, male, white, unmarried, with somewhat more education and income, to like doing risky things and to have used other drugs (Tables 1 and 2).

Lifetime psychedelic use

Lifetime psychedelic use was not associated with any of the indicators of mental health problems (aOR range 0.7-1.1). Rather, lifetime psychedelic use was associated with a lower likelihood of past year inpatient mental health treatment (aOR 0.8, 95% confidence interval (CI) 0.6-0.9, p=0.01) (Figure 1, Table 3). In our previous study this association was not statistically significant (aOR 0.9, 95% CI 0.7-1.2, p=0.53). Including respondents with missing data (with missing values set to the most common response) or excluding Native Americans (who may use peyote in a religious setting) did not substantially change the results.

Specific psychedelic use

Among the specific psychedelics (lifetime use of LSD, psilocybin, mescaline/peyote or peyote; past year use of LSD), we found 10 associations with a lower likelihood and one association with a greater likelihood of mental health problems (Table 4). Four of these associations were also statistically significant in our previous population study.

Associations between psilocybin use and lower likelihood of past year serious psychological distress, inpatient mental health treatment and psychiatric medication prescription were statistically significant both in this study (aOR 0.9, p=0.007; aOR 0.7, p=0.0004; aOR 0.8, p=0.002, respectively) and in our previous study (aOR 0.8, p=0.009; aOR 0.8, p=0.04; aOR 0.8, p=0.00008, respectively) (Krebs and Johansen, 2013b). Past year use of LSD was, with weak statistical significance, associated with lower likelihood of serious psychological distress (aOR 0.8, *p*=0.04); this was also consistent with our previous study (aOR 0.7, *p*=0.009).

Mescaline/peyote use was, with weak statistical significance, associated with a greater likelihood of past year symptoms of major depressive episode (aOR 1.2, *p*=0.02); however, mescaline/peyote use was not associated with diagnosis of depression (aOR 1.0, *p*=0.59) and peyote (mescaline-containing cactus) use was not associated with either symptoms of major depressive episode or diagnosis of depression (aOR 1.1, *p*=0.24; aOR 0.9, *p*=0.60, respectively). Furthermore, in our previous study, neither mescaline/peyote use nor peyote use was associated with past year symptoms of major depressive episode (aOR 0.9, *p*=0.14; aOR 0.9, *p*=0.67, respectively).

aOR: adjusted odds ratio (values less than 1.0 indicate lower likelihood); CI: confidence interval.
Bold text indicates $p < 0.05$.
[a] Adjusted for age (11 categories, treated as a continuous variable), gender (male, female), race/ethnicity (white, Hispanic, black, Asian, Native American, Native Hawaiian or Pacific Islander, more than one), household income (less than US$20,000, US$20,000-49,999, US$50,000-74,999, US$75,000 or more), education (not high school graduate, high school graduate, some college, college graduate), marital status (unmarried, married), likes to test self by doing risky things (never, seldom, sometimes, always), depressive episode before age 18 years (no, yes), and 10 types of lifetime drug use (cannabis/marijuana, opiates, cocaine, sedatives/tranquilizers, stimulants, MDMA/ecstasy, inhaled anesthetics, amyl nitrates, other inhalants, phencyclidine)

Stratified subgroups

In the stratified subgroups there were eight associations between psychedelic use and a decreased likelihood of various past year mental health problems, most with weak statistical significance, and none consistent with the stratified subgroups in our previous population study (Table 5). Notably, among people with a history of childhood depressive episode (before age 18 years), psychedelic use was associated with a lower likelihood of suicidal thoughts (aOR 0.8, *p*=0.01) and suicidal plan (aOR 0.5, *p*=0.002). Data on childhood depression and past year suicidal behavior were not available in our previous population study.

Discussion

Lack of associations with mental health or suicidality

We failed to find any associations between lifetime use of psychedelics and past year serious psychological distress, receiving or needing mental health treatment, depression, anxiety, or suicidal thoughts or behavior in the past year. Rather, lifetime use of psychedelics was associated with decreased inpatient psychiatric treatment. In addition to not being significantly different from no association, in all cases the calculated aORs were small (for all, psychedelic use aOR < 1.2).

Stratifying by age, gender, past year illicit drug use or childhood depressive episode did not substantially change the results of any of the logistic regression analyses. Likewise, lifetime use of LSD, psilocybin, mescaline or peyote, or past year use of LSD was not associated with a higher rate of mental health problems.

Most claims about the harms from psychedelics have been based on theoretical assumptions and case reports, which should be evaluated with caution. See our earlier population study of mental health among psychedelic users for further discussion about case reports and previous studies (Krebs and Johansen, 2013b).

The idea of 'flashbacks' and 'hallucinogen persisting perceptual disorder'

In particular, our previous population study (Krebs and Johansen, 2013b) did not support either the idea of 'flashbacks', described in extreme cases as recurrent psychotic episodes, hallucinations, or panic attacks, or the more recent 'hallucinogen persisting perceptual disorder' (HPPD), described as persistent visual phenomena with accompanying anxiety and distress, since lifetime use of psychedelics and past year use of LSD was not associated with past year symptoms of visual phenomena ('seeing something others could not'), panic attacks, psychosis or overall serious psychological distress. Recent randomized controlled trials with psilocybin have not reported any cases of flashbacks or persistent visual phenomena (Griffiths *et al.*, 2008, 2011; Studerus *et al.*, 2011). Interviews with over 500 regular participants in Native American peyote ceremonies did not identify anyone with flashbacks or persistent visual symptoms (Halpern *et al.*, 2005). Occasional visual phenomena are common in the general population, and all of the symptoms included in the purported HPPD are also present in people who have never used psychedelics. A recent study of 120 US adults troubled by HPPD-like persistent visual symptoms found a lower than average rate of psychedelic use (Schankin *et al.*, 2014). Overall, the validity of the HPPD diagnosis remains scant. HPPD may fit within the somatic symptom disorders. For further discussion, see Krebs and Johansen (2013b).

Psychedelics and personally significant experiences

Our results might reflect beneficial effects of psychedelic use, relatively better initial mental health among people who use psychedelics or chance 'false positive' findings. However, it is well documented that psychedelics elicit spiritual experiences. Indeed, long-term psychological benefits have been reported in several clinical trials of LSD, for example, 'About half of the total sample felt they had achieved more understanding and acceptance of themselves and a broader tolerance of the view points of others via the LSD experience' (McGlothlin and Arnold, 1971). In a recent randomized controlled trial of psilocybin, most of the participants (67%) regarded the experience as one of the most personally significant moments in their lives (comparable to the birth of a first child) (Griffiths *et al.*, 2006) and, furthermore, most of the participants (64%) reported improved wellbeing or life satisfaction 14 months later (Griffiths *et al.*, 2006, 2008; MacLean *et al.*, 2011). People often report long-term benefits from LSD use (Morgan *et al.*, 2010). No serious adverse events have been reported in recent randomized controlled trials of psilocybin, demonstrating that psychedelics can be administered safely in medical contexts (Griffiths *et al.*, 2008, 2011; Johnson *et al.*, 2008; Studerus *et al.*, 2011). Case-control and longitudinal studies have not found evidence of increased mental health problems among people who have used traditional psychedelics (peyote or ayahuasca) hundreds of times in legally recognized religious ceremonies (Bouso *et al.*, 2012; Halpern *et al.*, 2005).

Limitations

This study had a retrospective, cross-sectional design, making it impossible to draw causal inferences. Many potentially important risk factors, such as family mental health history, were not available. Longitudinal data were not available on mental health or other factors before psychedelic use. We cannot exclude the possibility that use of psychedelics might have a negative effect on mental health for some individuals or groups, which might be counterbalanced at a population level by a positive effect on mental health for others. People who choose to use psychedelics might have better initial mental health before using psychedelics, and people who experience problems apparently related to psychedelics may choose to not use them again. We did not adjust for multiple comparisons, so some of the associations with weak statistical significance are likely due to chance. Screening questions, rather than diagnostic interviews, were used as symptom indicators. We did not have data on setting of use or factors that might influence the experience of psychedelics. The study also relied on self-reports of drug use. Participants' answers to the questions on behaviors and mental health could be influenced by memory errors and under-reporting; however, a 14-year longitudinal study reported good consistency over time in reporting of LSD use (Johnston and O'Malley, 1997). Use of dimethyltryptamine (DMT), found in the shamanic brew ayahuasca, could not be determined from the data set; however, recent studies of people who have used ayahuasca hundreds of times have not detected evidence of problems (Bouso *et al.*, 2012). Dosage and purity of street drugs is often unknown and, in particular, substances sold as mescaline often contain LSD or other substances (Laing and Siegel 2003). A small group (< 2%) of US adults in prison, hospital or military service was not included in the NSDUH sampling.

Lack of association with suicidal behavior

This study did not find any associations between psychedelic use and increased likelihood of past year suicidal thoughts, plans or attempts. Rather, among people with childhood depression, those who had used psychedelics had lower likelihood of past year suicidal thoughts and plans.

There is little evidence linking psychedelic use to later suicide. A study of 178 adolescents with psychosis reported that suicide attempt was more likely among those who had used LSD, but there was no adjustment for other factors and it was not recorded whether the suicide attempt occurred before or after LSD use (Shoval *et al.*, 2006). A case-control study of 96 adolescents with depression reported that suicide attempt was more likely among those with hallucinogen abuse or dependence, but 'hallucinogen' was not defined and likely included drugs such as MDMA and PCP, there was little adjustment for other factors, and it was not recorded whether the suicide attempt occurred before or after hallucinogen use (Kelly *et al.*, 2002).

In the past, some people seem to have assumed that taking psychedelics, or indeed engaging in any introspective practice, could lead to depression and suicide because of the supposedly disturbing and disappointing nature of self-knowledge (Evang, 1968); however, there now seems to be greater acceptance of introspective practices (such as 'mindfulness' or meditation) among the public and mental health professionals. In a small number of publicized cases, relatives or anti-psychedelic campaigners have blamed an individual's suicide on prior psychedelic use, without evidence of any clear connection. For instance, in 1909 a Native American peyote church member killed himself (Stewart, 1987), and his death was then cited as evidence against peyote; in the 1960s there were a few cases where relatives blamed a suicide on prior LSD use (Mikkelson and Mikkelson, 2005). In surveys of US, Canadian and British physicians who administered LSD to thousands of psychiatric patients in the 1950s, 1960s and 1970s, a small number of suicides and suicide attempts were reported (in people with prior suicide attempt or serious mental illness) in the year or so after taking a dose of LSD (Canada Department of National Health and Welfare, 1973; Cohen 1960; Malleson 1971; US Senate, Committee on Government Operations, Subcommittee on Executive Reorganization, 1968). Based on these and other studies, the rate of adverse events following clinical treatment with LSD was considered to be similar to that expected among psychiatric patients in general, and overall LSD was considered to have acceptable safety for clinical use (Canada Department of National Health and Welfare, 1973; Home Office, Department of Health and Social Security, 1970; US Senate, Committee on Government Operations, Subcommittee on Executive Reorganization, 1968).

When evaluating case reports of suicide in psychedelic users, it is important to note that suicide is one of the most common causes of death in the general population: approximately two out of every 100 people in the US will die by suicide (CDC, 2013). Cases of suicide or death due to other causes during the direct effects of psychedelics are extremely rare, despite the fact that millions of doses are consumed annually (EMCDDA, 2011). It is of note that many of the stories from 50 years ago about death or injury of people while on LSD appear to be unsubstantiated urban legends (Siff, 2008).

Comments on the history of national and international control of psychedelics

Concern about psychedelic use seems to have been based on media sensationalism, lack of information and cultural biases, rather than evidence-based harm assessments. As examples of cultural biases, a 1967 case series of five university students with 'prolonged adverse reactions' to peyote consisted of a homosexual student who started a relationship with another male student, a student with pre-existing depression who wanted to travel to India and study Eastern religions, a student who left school and became a 'beatnik', a student who was prompted to seek psychotherapy for pre-existing social anxiety and paranoia about homosexuals, and an engineering student who had visions while falling asleep and eventually took a break from school to do volunteer work (Kleber, 1967). There was a common view in the early 20th century that mystical or transcendent experiences were, almost by definition, delusional and anti-scientific, and that self-exploration without the supervision of a trained therapist was dangerous (Evang, 1968; Hayman, 1964). While discussing psychedelics, psychiatrist Max Hayman wrote, 'The practices of the Christian mystics constitute one of the most tragic chapters of human history... Science is the path we have chosen to aid in man's growth and development, and mysticism in whatever guise is a contaminant of the scientific attitude' (Hayman, 1964). In an influential 1966 *Time* magazine interview, psychiatrist Sidney Cohen, one of the most prominent critics of the emerging psychedelic culture, commented on his own LSD experience: 'I got a massive jolt that I'll never forget. I got a chance to really look at myself, and I didn't like some of the things I saw' (*Time*, 1966).

The original World Health Organization (WHO) assessment of psychedelics, prepared for the 1971 Convention on Psychotropic Substances, claimed that psychedelics caused a list of problems; however, the references cited included no evidence of harm from psilocybin, mescaline or DMT, and only a small number of case reports and anecdotes of possibly LSD-related adverse effects (Isbell and Chrusciel, 1970; WHO Expert Committee on Drug Dependence, 1969). Central to the argument for international restrictions on psychedelics was the claim that psychedelics caused a special 'LSD-type' dependence, defined as 'periodic' use amongst 'arty-type' people (Eddy *et al.*, 1965; Isbell and Chrusciel, 1970; WHO Expert Committee on Drug Dependence, 1969). Psychedelics were claimed to have 'high abuse potential' simply because there were reports of their use (Isbell and Chrusciel, 1970). The WHO report acknowledged that LSD and other psychedelics 'are usually taken in the hope of inducing a mystical experience leading to a greater understanding of the users' personal problems and of the universe' and that people diagnosed with mental disorders following psychedelic use 'are generally believed to have been persons who were "predisposed" to psychiatric disease' (Isbell and Chrusciel, 1970).

As noted recently by the British Medical Association (BMA), 'The cultural and social attitudes surrounding illegal drugs mean that their classification and legal status do not directly relate to the health risks they pose to users and communities' (BMA, 2012). A 1970 assessment of LSD by the UK Home Office acknowledged that use of LSD and other psychedelics was a sincere spiritual practice, noting, 'We have been content to accept the sincerity of those of our witnesses who claimed that some people have reached a greater awareness and insight into their own problems and, indeed, into the meaning of life itself, through their use of LSD'. The UK assessment explained that 'there is a presumption in favour of allowing adult men and women to consume whatever substances they please, but this presumption must be overridden in circumstances in which such freedom results in a serious danger to public health... [Evidence for which] would have to be kept under continual review in the light of rapidly developing scientific knowledge and accelerating social change' (Home Office, Department of Health and Social Security, 1970). The only epidemiological data on non-clinical use of LSD included in the UK assessment was a table showing that 127 people who were admitted to UK psychiatric hospitals in 1966-1968 had reported having tried LSD at some point, not necessarily related to the hospital visit (Home Office, Department of Health and Social Security, 1970); these cases were a surely a tiny fraction of total psychiatric admissions or total LSD users at that time. We failed to find, in this study or in our previous population study, evidence linking past year LSD use to increased likelihood of inpatient mental health treatment (Krebs and Johansen, 2013b).

A 1975 report from the US National Institute of Mental Health noted that people who use LSD 'repetitively in a social pattern' 'cannot be characterized by any specific psychiatric label' and called for more 'scientific study of hallucinogen-derived mystical experiences... described as powerful and sometimes transforming' (Segal, 1975). A 1968 US Senate report on LSD policy noted that all expert witnesses were opposed to criminalizing LSD use and concluded: 'The tardy reaction of the Government was rash and excessive, resulting in the termination of almost all research... As protector of the public safety and supporter to medical research, the Government had an obligation to maintain a balanced perspective concerning LSD at a time of public tumult. It failed to do so' (US Senate Committee on Government Operations, Subcommittee on Executive Reorganization, 1968). LSD, psilocybin, mescaline and several other psychedelics are included in Schedule I of the US Controlled Substances Act of 1970; these substances were simply placed in Schedule I by Congress without an evidence-based assessment to determine whether LSD and other psychedelics met criteria to be added to Schedule I. There may have been a political rather than public health rationale behind the criminalization of psychedelic users. It is deeply troubling to read an interview with John Ehrlichman, advisor to US President Richard Nixon, in which he explains that the War on Drugs was 'really about' hurting 'the antiwar Left, and black people', and openly admits, 'Did we know we were lying about the drugs? Of course we did' (Baum, 2012).

Conclusions

The results of this study are consistent with our previous population study, early and recent randomized controlled trials, studies of regular participants in legally recognized psychedelic religious ceremonies, drug education materials from public agencies and recent expert assessments of drug harms (Krebs and Johansen, 2013b). There is little evidence linking psychedelic use to lasting mental health problems. In general, use of psychedelics does not appear to be particularly dangerous when compared to other activities considered to have acceptable safety. It is important to take a statistical perspective to risk, rather than focusing on case reports and anecdotes: 'Nothing in life is free from risk - risk is simply impossible to avoid... Even ordinary activities - eating breakfast, watching television, walking the dog - carry risks, however minor' (BMA, 2012). As Steven Pinker recently noted, 'In a free society, one cannot empower the government to outlaw any behavior that offends someone just because the offendee can pull a hypothetical future injury out of the air' (Pinker, 2008). Overall, it is difficult to see how prohibition of psychedelics can be justified from a public health or human rights perspective.

Abstract

Several lines of evidence suggest that classic (5-HT$_{2A}$ agonist) hallucinogens have clinically relevant effects in alcohol and drug addiction. Although recent studies have investigated the effects of psilocybin in various populations, there have been no studies on the efficacy of psilocybin for alcohol dependence. We conducted a single-group proof-of-concept study to quantify acute effects of psilocybin in alcohol-dependent participants and to provide preliminary outcome and safety data. Ten volunteers with DSM-IV alcohol dependence received orally administered psilocybin in one or two supervised sessions in addition to Motivational Enhancement Therapy and therapy sessions devoted to preparation for and debriefing from the psilocybin sessions. Participants' responses to psilocybin were qualitatively similar to those described in other populations. Abstinence did not increase significantly in the first 4 weeks of treatment (when participants had not yet received psilocybin), but increased significantly following psilocybin administration ($p < 0.05$). Gains were largely maintained at follow-up to 36 weeks. The intensity of effects in the first psilocybin session (at week 4) strongly predicted change in drinking during weeks 5-8 ($r = 0.76$ to $r = 0.89$) and also predicted decreases in craving and increases in abstinence self-efficacy during week 5. There were no significant treatment-related adverse events. These preliminary findings provide a strong rationale for controlled trials with larger samples to investigate efficacy and mechanisms.
TRIAL REGISTRATION: NCT02061293

Keywords: Addiction treatment, alcoholism, hallucinogens, psilocybin, clinical trial, motivational interviewing

Introduction

In the 1950s through early 1970s there was extensive research on the use of LSD and other classic (5-HT$_{2A}$ agonist or partial agonist) hallucinogens in the treatment of addiction (Abuzzahab and Anderson, 1971; Dyck, 2006; Grinspoon and Balakar, 1997; Halpern, 1996; Mangini, 1998), existential distress in dying patients (Grof *et al.*, 1973; Pahnke *et al.*, 1969; Richards, 1975; Richards *et al.*, 1977), pain (Kast, 1966; Kast and Collins, 1964), and other conditions (Grinspoon and Balakar, 1997; Grof, 2008). A recent meta-analysis (Krebs and Johansen, 2012) examined the six published randomized trials (Bowen *et al.*, 1970; Hollister *et al.*, 1969; Ludwig *et al.*, 1969; Pahnke *et al.*, 1970; Smart *et al.*, 1966; Tomsovic and Edwards, 1970) of LSD treatment of alcoholism. A total of 325 participants received active treatment with LSD, and 211 received control treatment. At the first post-treatment follow-up (ranging from 1 month to 12 months) the odds ratio for improvement was 1.96, favoring LSD (95% confidence interval 1.36-2.84, $Z = 3.59$, $p=0.0003$).

The past decade has seen a rapid growth of interest in potential clinical applications of the classic hallucinogen psilocybin (Bogenschutz, 2012; Burdick and Adinoff, 2013; Carhart-Harris *et al.*, 2012, 2013; Garcia-Romeu *et al.*, 2013; Grob *et al.*, 2011; Kometer *et al.*, 2012; Nichols, 2014). Using a double-blind, cross-over design, Grob *et al.* administered psilocybin 0.2 mg/kg vs. placebo to 12 patients with anxiety related to advanced cancer (Grob *et al.*, 2011). Participants showed significant improvement with time, and there were statistical trends suggesting a positive effect of psilocybin on mood. Additional clinical trials in cancer patients are currently nearing completion at Johns Hopkins University and New York University (Nichols, 2014). A recent pilot study of psilocybin as an adjunct in smoking cessation treatment resulted in remarkable rates of abstinence (80% point abstinence at 6-month follow-up) (Johnson *et al.*, 2014). Extensive clinical research with the classic hallucinogens (LSD, psilocybin, DMT, mescaline) has established their relative safety within a clinical research setting when subjects are carefully screened, supervised, and followed up (Strassman, 1984). A number of articles and chapters have reviewed the literature on the use of hallucinogens in the treatment of addictions (Abuzzahab and Anderson, 1971; Dyck, 2006; Grinspoon and Balakar, 1997; Halpern, 1996; Mangini, 1998), with the recent addition of two reviews that incorporate current research on the effects of classic hallucinogens more generally and discuss possible mechanisms of action (Bogenschutz and Pommy, 2012; Ross, 2012).

Biological mechanisms

Although classic hallucinogens bind to many serotonin receptor subtypes and other receptors (Ray, 2010), the psychoactive effects of all classic hallucinogens appear to depend primarily on their actions at 5-HT$_{2A}$ receptors (Nichols, 2004; Vollenweider and Kometer 2010; Vollenweider *et al*., 1998). Administration of classic hallucinogens in rat models has been shown to induce down-regulation of 5-HT$_{2A}$ receptors, particularly those in the anterior cingulate and frontomedial cortex, likely accounting for the rapid development and reversal of behavioral tolerance to most classic hallucinogens (Buckholtz *et al*., 1990; Gresch *et al*., 2005).

The behavioral correlates and effects of 5-HT$_{2A}$ receptor activity are complex. Increased 5-HT$_{2A}$ receptor binding has been found in relation to pathological conditions in humans including depression (Shelton *et al*., 2009), impulsive aggression (Rosell *et al*., 2010), neuroticism (Frokjaer *et al*., 2008), borderline personality disorder (Soloff *et al*., 2007), and suicide (Anisman *et al*., 2008). The relationship of 5-HT$_{2A}$ receptor binding/activity and alcoholism or alcohol exposure is less clear. Family history of alcoholism may be associated with lower 5-HT$_{2A}$ binding (Underwood *et al*., 2008), and alcoholism is not consistently associated with change in 5-HT$_{2A}$ receptor levels (Thompson *et al*., 2012; Underwood *et al*., 2008). Among alcoholics, one small post-mortem study reported that higher impulsivity was associated with increased 5-HT$_{2A}$ receptor binding (Thompson *et al*., 2012). In animal models, alcohol exposure has been associated with region-specific increases (Akash *et al*., 2008) and decreases (George *et al*., 2010) in 5-HT$_{2A}$ receptors binding. Studies indicate that increased activity in 5-HT$_{2A}$mediated pathways relative to 5-HT$_{2C}$ activity increases cue response and impulsivity in rat models of cocaine addiction (Cunningham and Anastasio, 2014). 5-HT$_{2A}$ antagonists suppress alcohol consumption in animal models (Johnson, 2008). However, two large trials of the 5-HT$_{2A}$ antagonist ritanserin failed to demonstrate beneficial effects in people with alcohol dependence (Johnson *et al*., 1996; Wiesbeck *et al*., 1999).

Animal studies suggest mechanisms by which acute activation of 5-HT$_{2A}$ receptors could activate intracellular signaling pathways resulting in persisting changes in cellular structure and synapses. The classic hallucinogen DOI increases expression of glial cell line-derived neurotrophic factor (GDNF) mRNA in glioiblastoma cells by a 5-HT$_{2A}$-dependent mechanism (Tsuchioka *et al*., 2008). Through its action on 5-HT$_{2A}$ receptors, DOI has also been shown to increase levels of mRNA for brain-derived neurotrophic factor (BDNF) in rat parietal cortex and other neocortical regions, with decreases in the hippocampus and no change in piriform cortex (Vaidya *et al*., 1997). These findings are relevant because levels of BDNF and GDNF are inversely related to alcohol consumption and conditioned place preference in animal models (Ghitza *et al*., 2010). DOI activates intracellular signaling cascades associated with dendritic spine remodeling on rat pyramidal cells, and transiently increases the size of dendritic spines on cortical neurons (Jones *et al*., 2009).

Psychological models of psychedelic treatment

Clinical work with classic hallucinogens has emphasized the central role of the altered state of consciousness experienced during the drug's acute effects (Grof, 2008; Hoffer, 1967; Masters and Houston, 2000; Pahnke *et al*., 1970; Sherwood *et al*., 1962). The "psycholytic" model of treatment emphasized the use of classic hallucinogens to enhance the process of psychodynamic psychotherapy by making unconscious material more accessible (Leuner, 1967). The "psychedelic" treatment model on the other hand emphasized the use of relatively high doses of classic hallucinogens (usually LSD) to occasion a "peak-psychedelic" or mystical experience of ego loss, often likened to psychological death and rebirth (Kurland *et al*., 1967). The latter model was used in most of the clinical studies conducted in North America using LSD in the treatment of addiction or existential anxiety in the dying. The concept of a singular transformative experience leading to lasting behavior change is consistent with classic descriptions of religious conversion (James, 1902), "spiritual awakening" in the context of Alcoholics Anonymous (Forcehimes, 2004), and spontaneous Quantum Change experiences (Miller and C'de Baca, 2001). Recent studies have demonstrated that the self-reported "mystical" dimension of the psilocybin experience (feelings of unity, sacredness, ultimate reality, transcendence of time and space, deeply felt positive mood, and ineffability (Pahnke, 1963)) significantly predicts the lasting personal significance of the experience (Griffiths *et al.*, 2008) and personality change (Maclean *et al.*, 2011) in normal volunteers receiving psilocybin.

The evidence summarized above provides a convincing rationale for investigating whether a classic hallucinogen can improve treatment response among patients with alcohol dependence. In spite of the accumulating evidence that psilocybin has clinically relevant effects and is safe under controlled conditions, there are no prior studies of psilocybin in the treatment of alcohol dependence. We therefore undertook a proof-of-concept study which aimed to quantify the psychoactive effects and tolerability of oral psilocybin in alcohol-dependent participants, and to evaluate outcomes during and after completion of treatment.

Methods

Study design

The study employed a single-group, within-subjects design. Participants received a 12-week, 14-session manualized intervention including two open-label psilocybin sessions in which psilocybin was administered: the first after 4 weeks of psychosocial treatment, the second after 8 weeks. Outcome data were collected for a total of 36 weeks.

Participants

Participants were recruited from the community using advertisements in local media and flyers. They were males and females age 25-65 with a diagnosis of active alcohol dependence, ascertained using the Structured Clinical Interview for DSM-IV (SCID) (First *et al.*, 1996), and at least two heavy drinking days in the past 30 days, who were concerned about their drinking and not currently in treatment. Participants were excluded if screening showed them to have exclusionary medical or psychiatric conditions; family history of schizophrenia, bipolar disorder, or suicide; cocaine, psychostimulant, or opioid dependence; or history of using hallucinogens more than 10 times (or any use in the past 30 days). Participants were required to be abstinent and not in alcohol withdrawal at the time of the psilocybin sessions. Participants provided written informed consent, and all study procedures were reviewed and approved by the IRB of the University of New Mexico Health Sciences Center.

Interventions

Psychosocial intervention

The psychosocial intervention comprised a total of 12 sessions: seven sessions of Motivational Enhancement Therapy (MET: a structured approach using the principles of motivational interviewing (Miller and Rolnick, 2013)), three preparation sessions, and two debriefing sessions. Four sessions occurred before the first psilocybin session, four sessions between the first and second psilocybin sessions, and four sessions after the second psilocybin session. The psychosocial intervention was conducted by a team of two therapists. One performed the seven MET sessions focused on changing drinking behavior, while the other was responsible for preparation before, support during, and debriefing after the psilocybin sessions. Both therapists were present for the preparation and debriefing sessions, as well as the psilocybin sessions. Three of the authors (MB, AF, CW) served as study therapists. Therapy sessions were audiorecorded. The first and third MET sessions were coded using the Motivational Interviewing Treatment Integrity (MITI 3.1) coding system (Moyers *et al.*, 2005) by a rater trained to reliability.

Dosing and administration of study medications

On the morning of the psilocybin sessions, participants were required to be afebrile, non-hypertensive, non-tachycardic, abstinent from alcohol for at least 24 hours, and without evidence of alcohol withdrawal. Urine drug screens were negative for cocaine, psychostimulants, and opioids, and breath was negative for alcohol.

The psilocybin sessions took place in a room that was specially prepared to provide a living-room-like environment for the sessions. Individualized doses of psilocybin (based on participant weight) were prepared by the study pharmacist on the morning of the session, and placed in a single gelatin capsule. Participants ingested the psilocybin capsule followed by 4 ounces of water. They were instructed to lie on a couch wearing eyeshades and headphones (providing a standardized program of music), and to direct their attention toward their internal experience. Participants remained under observation for at least 8 hours following psilocybin administration. Both therapists were present throughout the session. Interactions with the participants were supportive and non-directive. Medications were available for administration if needed to treat hypertension (sublingual nitroglycerin 0.4 mg), anxiety (lorazepam 1-2 mg PO/IM), or acute psychosis (ziprasidone 10-20 mg PO/IM). Beginning 7 hours after drug administration, participants completed questionnaires and assessments, and a brief clinical interview was performed, including mental status exam. Participants were escorted home at the end of the session by a family member or friend, who stayed with the participant overnight.

For the first psilocybin session, participants received a dose of 0.3 mg/kg. For the second session, the dose was increased to 0.4 mg/kg unless the participant (i) was unwilling to increase the dose; (ii) experienced adverse effects during the first session which suggested that a higher dose would pose significant risk; or (iii) reported a "complete" mystical experience during the first session (Griffiths *et al.*, 2006), indicating very strong effects from 0.3 mg/kg.

Assessments

Medical evaluation

Medical screening consisted of medical history and physical examination, ECG, liver function tests, complete blood count, blood chemistries, urinalysis, serum pregnancy test, and body mass index. Women of childbearing potential completed a menstrual calendar at each assessment visit, and urine pregnancy tests were completed prior to each drug administration session. The Clinical Institute Withdrawal Scale - Alcohol, revised (CIWA-Ar) (Sullivan *et al.*, 1989) was used to assess alcohol withdrawal at screening and before the psilocybin sessions.

Psychiatric and substance use disorder diagnoses

The SCID (First *et al.*, 1997) was used to diagnose DSM-IV Axis I disorders including substance abuse and dependence diagnoses.

Acute hallucinogen effects

Self-report scales (administered 7 hours after drug administration) and monitor ratings (0-6 hours after drug administration) were used to quantify acute subjective effects. The Intensity subscale of the Hallucinogen Rating Scale (HRS) (Strassman *et al.*, 1994) was used as a global measure of the intensity of the drug experience. The 5-Dimensional Altered States of Consciousness Scale (5D-ASC) (Dittrich, 1998) has 94 items using the visual analog scale format, yielding five primary dimensions: "Oceanic Boundlessness," "Dread of Ego Dissolution," "Visionary Restructuralization," "Auditory Alterations," and "Altered Vigilance." The States of Consciousness Scale is a 100-item questionnaire which has been used extensively to measure states of consciousness in hallucinogen administration experiments (Griffiths *et al.*, 2006; Pahnke, 1963, 1969; Richards *et al.*, 1977; Turek *et al.*, 1974). This scale contains the 43 items of the Pahnke-Richards Mystical Experience Questionnaire (MEQ) (Griffiths *et al.*, 2006). The Addiction Research Center Inventory (ARCI), 49-item version (Martin *et al.*, 1971) was also administered following each drug administration session. In addition, a Monitor Session Rating Form (Griffiths *et al.*, 2006) was completed by both monitors at intervals during the psilocybin sessions to provide ratings of participants' behavior and affect during the session.

Substance use and consequences

The Time-Line Follow-Back (TLFB) (Sobell and Sobell, 1992, 1995) procedure was used to assess drinking behavior at baseline (covering the 12 weeks preceding enrollment) and follow-up visits. Heavy drinking days were defined as days during which participants consumed five or more standard drinks if the participant was male, or four or more standard drinks if the participant was female, a standard drink being defined as 14 g of alcohol. Drinking days were defined as days during which participants consumed any amount (even a sip) of an alcoholic beverage. The Short Inventory of Problems (SIP) (Miller *et al*., 1995), past 3 month version, was used to measure consequences of alcohol use. Breath Alcohol Concentration (BAC) was measured at each visit, but was used to ensure safety of treatment and validity of assessments rather than as an outcome measure.

Psychological assessments

The Stages of Change Readiness and Treatment Eagerness Scale (SOCRATES 8A) (Miller and Tonigan, 1996) was used as a measure of motivation. The Alcohol Abstinence Self-Efficacy Scale (AASE) (Diclemente *et al*., 1994) was used as a measure of self-efficacy to abstain from drinking. The Penn Alcohol Craving Scale (PACS) (Flannery *et al*., 1999) was used to assess craving. The Profile of Mood States (POMS) (Mcnair *et al*., 1981) was used as a measure of mood. Additional measures of persisting psychological effects obtained but not discussed in this publication were the Hood Mysticism Scale (Hood *et al*., 2001), the Persisting Effects Questionnaire (Griffiths *et al*., 2006), the ASPIRES Spiritual Transcendence Scale (Piedmont, 1999), the Brief Multidimensional Measure of Religiousness/Spirituality (Fetzer Institute, 1999), the NEO Personality Inventory 3 (NEO-PI-3) (Mccrae *et al*., 2005), and the Schwartz Value Survey (Schwartz, 1992, 2006).

Safety assessment

Vital signs were obtained at each visit and measured frequently during psilocybin sessions: every half hour for the first 2 hours, then hourly for the next 4 hours, with more frequent readings as needed. Adverse events (AEs), when present, were collected on an AE case report form at the end of the psilocybin sessions and at all subsequent visits, including assessment of clinical significance and relatedness to treatment.

Statistical analysis and power

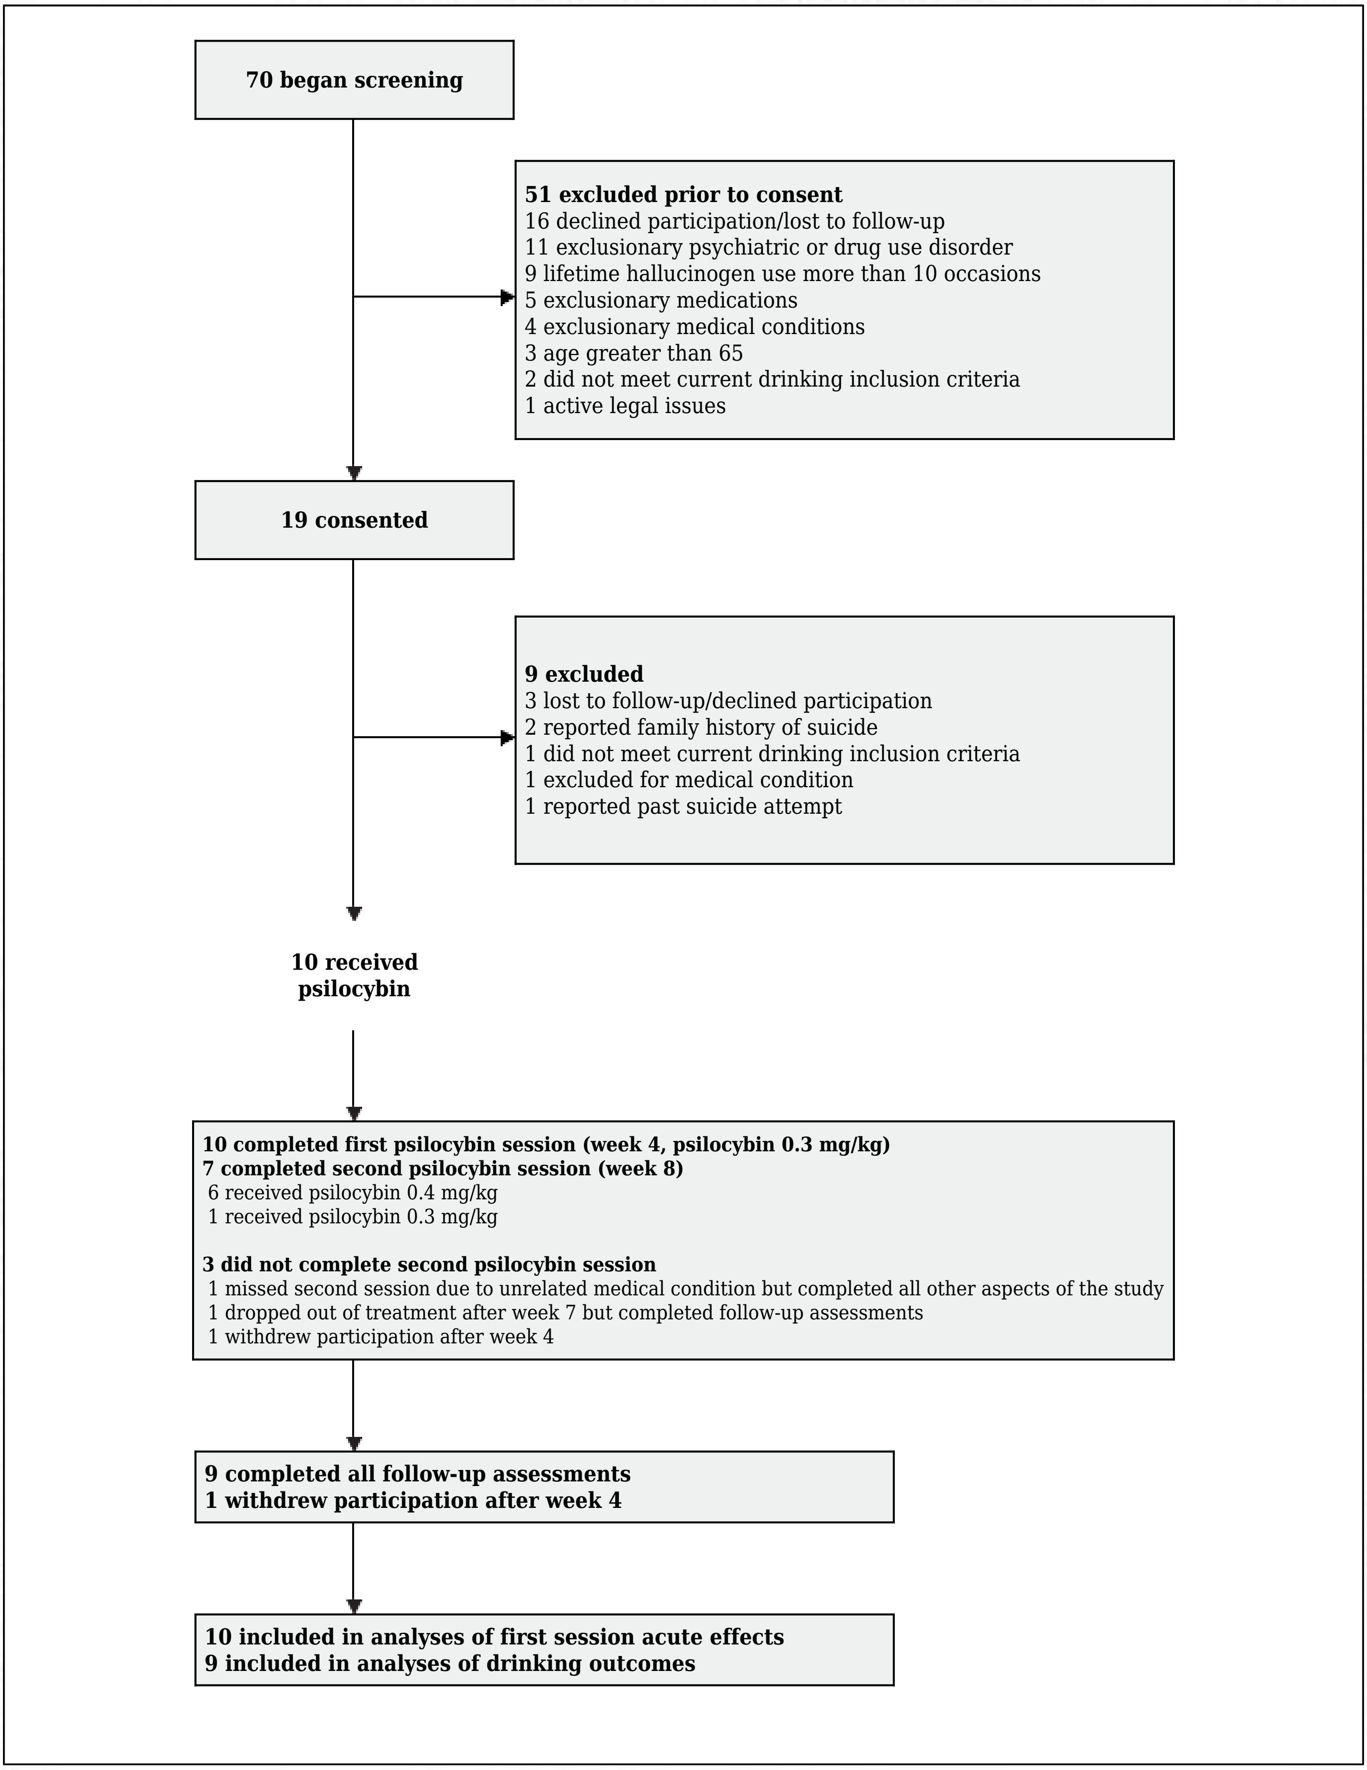
Statistical analyses for this open-label pilot study were primarily descriptive, but two *a priori* hypotheses were tested. To test for changes in drinking behavior (percent heavy drinking days and percent drinking days), consequences of drinking, and psychological outcomes, scores at follow-up time points were contrasted with baseline and week 4 values using paired t-tests, and effect sizes (Cohen's d) (Cohen, 1988) were computed with correction for correlation between time points (Morris and Deshon, 2002). The primary drinking outcome was percent heavy drinking days, and the primary contrast was baseline vs. weeks 5-12. With a sample size of $n = 10$, the study had power of 0.803 to detect pre-post changes of effect size $d = 1.0$, with $\alpha = 0.05$ (2-tailed) prior to correction for multiple comparisons. For drinking outcomes, the Benjamini-Hochberg procedure (Benjamani and Hochberg, 1995) was used to control the false discovery rate at the 0.05 level.

Results

Participants

In total 70 individuals were screened for the study, of whom 10 were included in the study (Figure 1). Participants were four women and six men with DSM-IV alcohol dependence. Two participants were Native American/Alaska Native, one was African American, four were Hispanic, and three were white non-Hispanic. Four were single, three were married, and three were divorced. Four were working full-time, five part-time, and one was unemployed. Mean household income was $47,023 (SD $35,262). Participants averaged 15.1 (SD 3.7) years of education (12 years representing graduation from high school), and three were college graduates.

Mean age was 40.1 years (SD 10.3, range 25-56), and mean duration of alcohol dependence was 15.1 years (SD 11.5, range 4-32). Participants had a mean of 5.0 dependence criteria (SD 1.2, range 3-7). Eight out of 10 had evidence of physical dependence (tolerance or withdrawal), but none had alcohol withdrawal symptoms requiring treatment during the trial.



70 began screening
51 excluded prior to consent
16 declined participation/lost to follow-up
11 exclusionary psychiatric or drug use disorder
9 lifetime hallucinogen use more than 10 occasions
5 exclusionary medications
4 exclusionary medical conditions
3 age greater than 65
2 did not meet current drinking inclusion criteria
1 active legal issues
19 consented
9 excluded
3 lost to follow-up/declined participation
2 reported family history of suicide
1 did not meet current drinking inclusion criteria
1 excluded for medical condition
1 reported past suicide attempt
10 received psilocybin
10 completed first psilocybin session (week 4, psilocybin 0.3 mg/kg)
7 completed second psilocybin session (week 8)
6 received psilocybin 0.4 mg/kg
1 received psilocybin 0.3 mg/kg
3 did not complete second psilocybin session
1 missed second session due to unrelated medical condition but completed all other aspects of the study
1 dropped out of treatment after week 7 but completed follow-up assessments
1 withdrew participation after week 4
9 completed all follow-up assessments
1 withdrew participation after week 4
10 included in analyses of first session acute effects
9 included in analyses of drinking outcomes

Figure 1. Participant flow.

Treatment exposure and follow-up

Figure 1 summarizes participation in treatment and follow-up. Ten participants completed the first psilocybin session. Of the seven participants completing the second psilocybin session, six received psilocybin 0.4 mg/kg and are included in analysis of second session effects. One received psilocybin 0.3 mg/kg due to meeting criteria for "complete mystical experience" in the first session. Nine participants completed all follow-up assessments and are included in outcome analyses. One participant discontinued participation shortly after the first psilocybin session and did not provide usable outcome data. A total of 14 MET sessions were coded for fidelity using the MITI 3.1. Mean (SD) global scores ranged from 4.43 (0.76) to 5.00 (0.00), well above the proficiency benchmark of 4.0.

Acute effects

Figure 2 illustrates physiologic effects and monitor ratings during the first psilocybin session, in which all participants received psilocybin 0.3 mg/kg, and during the second psilocybin session for the six participants who received psilocybin 0.4 mg/kg. Systolic or diastolic blood pressure was modestly but significantly increased from 30 minutes to 180 minutes in one or both conditions. Heart rate (not shown) did not change significantly. Monitor ratings of global drug effect and "distance from ordinary reality" peaked between 120 and 180 minutes, and were significantly elevated at most time points. Differences in these measures between the two doses were not statistically significant (paired *t*-tests, df = 5).

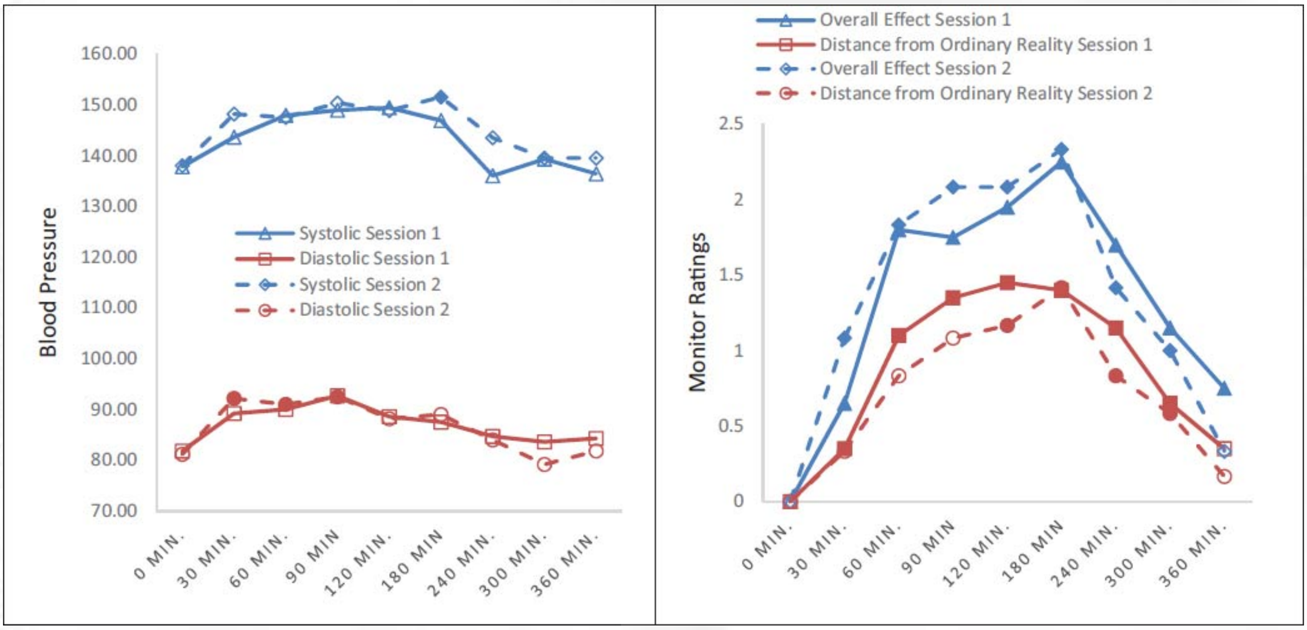


Figure 2. Within-session objective effects. Blood pressure (mm Hg) monitor ratings (0-4 Likert Scale).
Means are shown for 10 participants receiving psilocybin 0.3 mg/kg in the first session (solid lines), and the six participants who received psilocybin 0.4 mg/kg in the second session (*n* = 6, dashed line) during the 6 hours following drug administration. Solid markers indicate significant difference from baseline value.

Table 1 shows mean scores on self-report measures of subjective experience obtained 7 hours following administration of psilocybin 0.3 mg/kg in the first session and for the six participants who received psilocybin 0.4 mg/kg in the second session. Intensity of effects varied markedly from patient to patient. On average, acute effects on the MEQ and HRS are numerically lower in magnitude than those seen at comparable doses in normal volunteers (Griffiths *et al*., 2011). For the six participants who received psilocybin 0.4 mg/kg in the second session, subjective ratings were not significantly different between the two sessions (paired *t*-tests, df = 5), but were strongly correlated between the sessions for most of the scales intended to measure hallucinogen effects.

Clinical outcomes

Percent heavy drinking days decreased during weeks 5-12 relative to baseline (mean difference (SD) = 26.0 (22.4), 95% CI 8.7-43.2, t(8) = 3.477, p=0.008), and also decreased relative to weeks 1-4 (during psychosocial treatment but prior to psilocybin) (mean difference (SD) = 18.2 (20.0), 95% CI 2.8-33.5, t(8) = 2.723, p=0.026). Percent drinking days also decreased during weeks 5-12 relative to baseline (mean difference (SD) = 27.2 (23.7), 95% CI 9.0-45.4, t(8) = 3.449, p=0.009) and relative to weeks 1-4 (mean difference (SD) = 21.9 (21.8), 95% CI 5.1- 38.6, t(8) = 3.010, p=0.017). Figure 3 illustrates change in percent heavy drinking days and percent drinking days over the course of the study. Improvement is not statistically significant during the first 4 weeks of participation, when participants received weekly counseling but had not yet received psilocybin. Following the first psilocybin session, percent heavy drinking days and percent drinking days are significantly lower than baseline at all follow-up points. Further, these measures are significantly decreased relative to weeks 1-4 with the exception of heavy drinking days during weeks 9-12 (p = 0.059). Fifteen out of 16 contrasts were significant at the nominal 0.05 level, and all of these remained significant at a false discovery rate of 0.05. Effect sizes are large (greater than 0.8) with one exception, Cohen's d ranging from 0.75 to 1.38. Table 2 summarizes additional outcomes for study participants. Significant improvement relative to baseline and/or week 4 is noted at multiple time points for drinking consequences, craving, self-efficacy, and motivation. Changes in POMS scores were not significant with one exception (increased Vigor at week 24 relative to baseline).

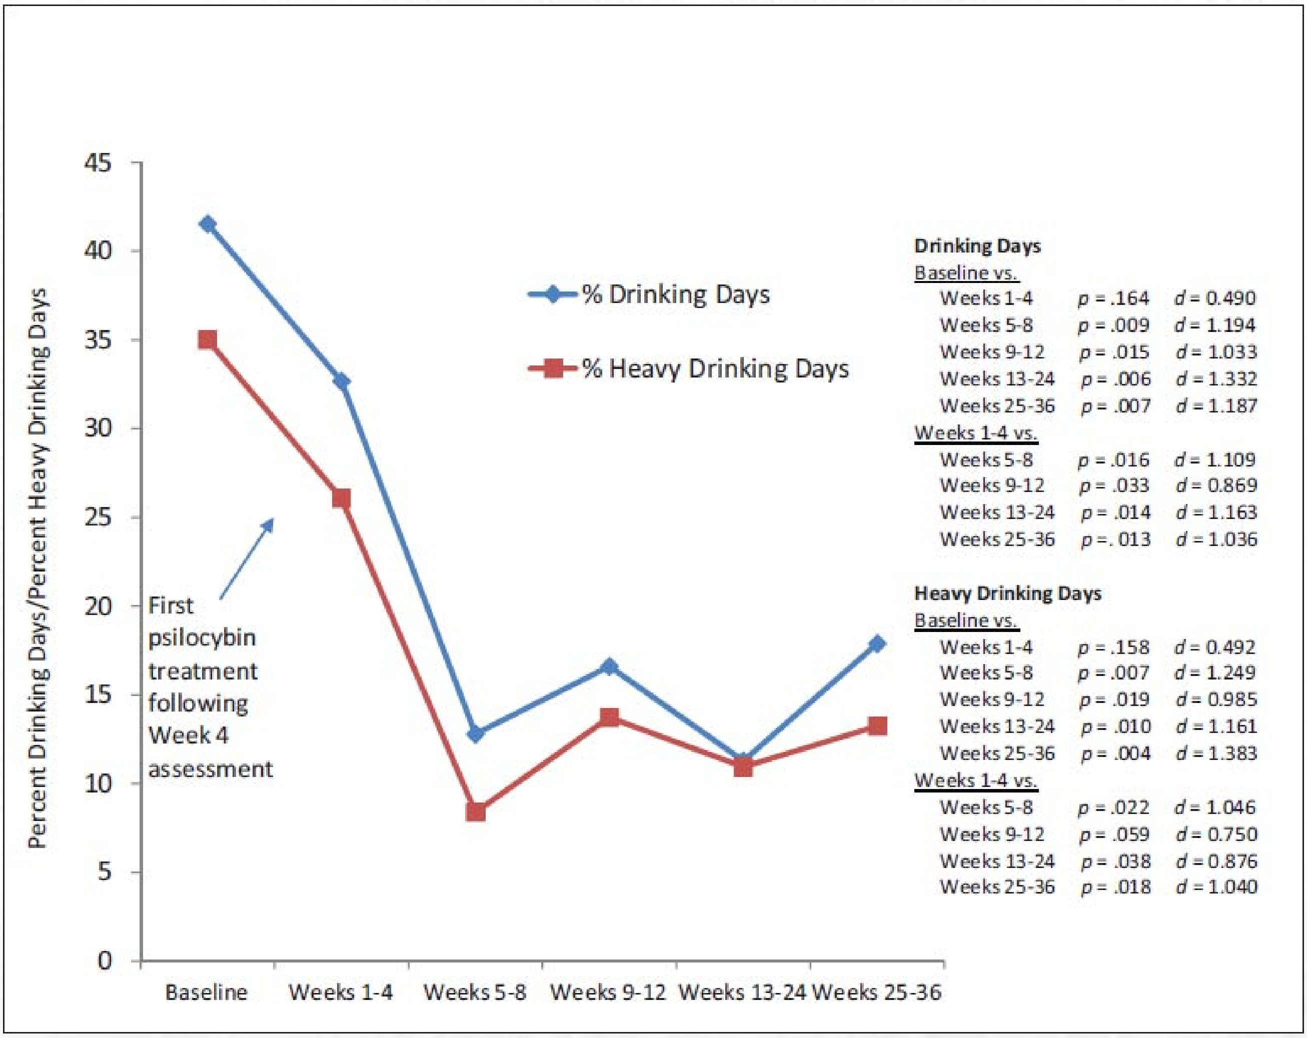

Figure 3. Drinking outcomes and effect sizes.
Means shown are for all available data (*n* = 10 at baseline, *n* = 9 at all other time points). p-values are from paired *t*-tests (df = 8). Cohen's *d* is shown for the contrast between baseline or weeks 1-4 and each follow-up time point.

Relationships between acute effects and treatment response

Because the acute effects of psilocybin were quite variable, it was possible to explore the relationships between the intensity of acute effects and changes in drinking behavior. Table 3 shows correlations between three summary measures of the intensity of acute effects in the first psilocybin session and short-term clinical outcomes. Large correlations were observed between measures of acute effect intensity and change in drinking behavior, as well as changes in craving and self-efficacy in some cases. Supplemental Figure 1 displays scatterplots of the individual data points underlying these correlations.

Table 3. Correlations between acute effects and change in drinking, craving, and self-efficacy (*n* = 9).

Treatment-related adverse events

Five participants reported mild headaches which resolved within 24 hours following psilocybin administration, consistent with prior reports (Johnson *et al.*, 2012). One participant had nausea with one episode of emesis during one psilocybin session. One participant with irritable bowel syndrome experienced diarrhea during one psilocybin session. One participant reported insomnia on the night following a psilocybin session. No participant required medication or other intervention for blood pressure, anxiety, or other psychiatric symptoms. There was no report of illicit hallucinogen use by any participant during study participation.

Discussion

Overall, the response of our alcohol-dependent participants to psilocybin was qualitatively similar to that which has been reported in other samples (Hasler *et al.*, 2004; Griffiths *et al.*, 2006, 2011; Grob *et al.*, 2011). Medication-related AEs were transient and mild. However, subjective response was highly variable among participants in this study, and numerically weaker on average for some of the measures than that reported in normal volunteers at comparable doses (Griffiths *et al.*, 2011). This is consistent with observations beginning in the 1950s that alcoholics tended to require larger doses of LSD to have a strong effect (Chwelos *et al.*, 1959). Our findings suggest that some alcohol-dependent patients are relatively insensitive to the effects of psilocybin, although larger samples will be necessary to confirm this. The lack of significant differences between the 0.3 mg/kg and 0.4 mg/kg doses is most likely accounted for by the small sample size ($n = 6$) and/or idiosyncratic responses in a small number of participants.

Participants exhibited significant improvement in drinking, with large pre-post effect sizes, as well as significant changes in psychological measures relevant to drinking. Importantly, much of the improvement occurred following the administration of psilocybin, at which time participants had already received 4 weeks of psychosocial treatment and 4-6 hours of assessment. Also, strong correlations were observed between measures of intensity of the acute drug effects and clinical outcomes. Although change in drinking was correlated with the mystical quality of the experience, it was similarly associated with ratings of other acute effects. More work will necessary to determine whether there are particular characteristics of the acute psilocybin experience that are predictive of therapeutic benefit in alcohol use disorder.

While clearly demonstrating feasibility, this study has major, self-evident limitations including small sample size, lack of a control group or blinding, and lack of biological verification of alcohol use. Due to these limitations, it is not possible to separate unequivocally the effects of attention, psychosocial treatment, and time; expectancy effects related to knowledge of receiving psilocybin; and the specific effects of psilocybin. However, the time course of the observed changes and the striking relationship between intensity of response and clinical improvement provide support for the concept that psilocybin may produce lasting benefits in alcohol use disorder when administered under controlled conditions to carefully screened patients, in the context of appropriate psychosocial interventions. Adequately powered randomized trials will be necessary to test this hypothesis rigorously. Neuroimaging studies in alcohol use disorder trial participants would help characterize the persisting effects of psilocybin on brain activity (e.g. resting state functional connectivity, cue response, stress response, response to emotional stimuli, and inhibitory control). Studying the genetics of response to psilocybin may shed light on the variability of response, ultimately aiding in dose selection or identifying patients particularly likely to benefit.

Acknowledgements

We wish to thank the following persons for their contributions to the study. From the University of New Mexico, Albuquerque, NM: for data collection, Rose C. Bigelow, MS; for fidelity monitoring, Christina E. Ripp, MA; for data entry and cleaning, Robert G. Voloshin, DO, Alex M. Pogzeba, BA, Christina E. Ripp, MA, Lindsay M. Worth, MPA; for quality assurance and regulatory compliance, Linda A. Schenkel; CCRC, CPhT; for service on the Data and Safety Monitoring Committee for the study, Jan A. Fawcett, MD, Theresa B. Moyers, PhD. From the University of North Carolina: for providing the psilocybin used for this study, David E. Nichols, PhD. From Johns Hopkins University: for providing training for study interventionists, William A. Richards, PhD; for guidance on intervention and assessment procedures, Roland R. Griffiths, PhD. From the Heffter Research Institute: for advice and support in the design and conduct of the study, George R. Greer, MD.

Declaration of Conflicting Interests

The authors declared the following potential conflicts of interest with respect to the research, authorship, and/or publication of this article: Dr. Bogenschutz reports grants from National Institute on Drug Abuse, during the conduct of the study; and grants from the Lundbeck Foundation and the Heffter Research Institute, outside the submitted work.

Funding

The authors disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: The study was supported by a grant from the Heffter Research Institute and NIH grant 1UL1RR031977.

Abstract

To date, pharmacological treatments for mood and anxiety disorders and for drug dependence show limited efficacy, leaving a large number of patients suffering severe and persistent symptoms. Preliminary studies in animals and humans suggest that ayahuasca, psilocybin and lysergic acid diethylamide (LSD) may have antidepressive, anxiolytic, and antiaddictive properties. Thus, we conducted a systematic review of clinical trials published from 1990 until 2015, assessing these therapeutic properties. Electronic searches were performed using the PubMed, LILACS, and SciELO databases. Only clinical trials published in peer-reviewed journals were included. Of these, 151 studies were identified, of which six met the established criteria. Reviewed studies suggest beneficial effects for treatment-resistant depression, anxiety and depression associated with life-threatening diseases, and tobacco and alcohol dependence. All drugs were well tolerated. In conclusion, ayahuasca, psilocybin and LSD may be useful pharmacological tools for the treatment of drug dependence, and anxiety and mood disorders, especially in treatment-resistant patients. These drugs may also be useful pharmacological tools to understand psychiatric disorders and to develop new therapeutic agents. However, all studies reviewed had small sample sizes, and half of them were open-label, proof-of-concept studies. Randomized, double-blind, placebo-controlled studies with more patients are needed to replicate these preliminary findings.

Keywords: ayahuasca, dimethyltryptamine, hallucinogens, LSD, psilocybin, tryptamines

Naturally occurring classical or serotonergic hallucinogens such as the tryptamines *N,N*-dimethyltryptamine (DMT) and psilocybin (4-phosphoryloxy-*N,N*-DMT) have a long history of ritual use in Latin America [Harner, 1976; Grispoon and Bakalar, 1981; Dobkin de Rios, 1984, 1990; Schultes, 1986, 1998; Wasson *et al*. 1986; Schultes and Hofmann, 1992; Furst, 1994; Ott, 1994, 2004; Guzmán, 2008; McKenna and Riba, 2016]. DMT was first synthesized in 1931 by the Canadian chemist Richard Manske and subsequently isolated by the Brazilian chemist Oswaldo Gonçalves de Lima in 1946 from *Mimosa hostilis*, a hallucinogenic plant used by northeastern Brazilian indigenous groups for the preparation of a sacred beverage called *jurema* [Ott, 1994, 1999, 2004; McKenna and Riba, 2016]. DMT is also the main psychotropic compound of ayahuasca, a psychotropic brew used for magico-ritual and therapeutic purposes by indigenous and urban populations of Amazonian countries such as Brazil, Colombia, Peru and Ecuador [Harner, 1976; Dobkin de Rios, 1984, 1990; Schultes, 1986, 1998; Schultes and Hofmann, 1992; Furst, 1994; Ott, 1994, 2004; McKenna and Riba, 2016].

Ayahuasca is usually obtained by boiling the stems of the liana *Banisteriopsis caapi* with the leaves of the shrub *Psychotria viridis* [Harner, 1976; Dobkin de Rios, 1984, 1990; McKenna *et al*. 1984; Schultes, 1986, 1998; Schultes and Hofmann, 1992; Furst, 1994; Ott, 1994, 1999, 2004; Riba *et al*. 2001, 2003; McKenna and Riba, 2016]. *P. viridis* is rich in DMT, while *B. caapi* contains β-carboline compounds that reversibly inhibit monoamine oxidase A (MAO-A), such as harmine, tetrahydroharmine (THH) and harmaline [Buckholtz and Boggan, 1977; Dobkin de Rios, 1984; McKenna *et al*. 1984; Schultes, 1986; Schultes and Hofmann, 1992; Ott, 1994, 1999, 2004; Riba, *et al*. 2001, 2003; McKenna and Riba, 2016]. Due to peripheral (gastrointestinal and liver) MAO-A degradation, DMT is not orally active [Riba *et al*. 2001, 2003, 2015; McKenna and Riba, 2016]. Thus, MAO-A inhibition by the β-carbolines in ayahuasca allows DMT to reach systemic circulation and the central nervous system [Ott, 1999; Riba *et al*. 2001, 2003, 2015; McKenna and Riba, 2016].

Psilocybin and its active dephosphorylated metabolite psilocin (4-hydroxy-*N,N*-DMT) are the primary psychoactive compounds of several species of hallucinogenic mushrooms found throughout the world [Harner, 1976; Grispoon and Bakalar, 1981; Wasson *et al*. 1986; Dobkin de Rios, 1990; Schultes and Hofmann, 1992; Furst, 1994; Schultes 1998; Passie *et al*. 2002; Ott, 2004; Guzmán, 2008; Tylš *et al*. 2014; McKenna and Riba, 2016]. Some of these species, such as *Psilocybe mexicana*, have a crucial role in the religious and medicinal systems of indigenous groups in Mexico [Harner, 1976; Grispoon and Bakalar, 1981; Wasson *et al*. 1986; Dobkin de Rios, 1990; Schultes and Hofmann, 1992; Furst, 1994; Schultes, 1998; Ott, 2004; Guzmán, 2008; McKenna and Riba, 2016]. The Swiss chemist Albert Hofmann first isolated psilocybin and psilocin from *P. mexicana* in 1958 after several self-experiments, and synthetized these compounds later in the same year [Passie *et al*. 2002; Ott, 2004; Hofmann, 2005; Guzmán, 2008; Tylš *et al*. 2014; McKenna and Riba, 2016]. Although psilocybin is usually referred to as being the main psychoactive compound in hallucinogenic mushrooms, it is in fact a so-called prodrug of psilocin. Thus, after ingestion, it is rapidly dephosphorylated in the gut and liver into the active metabolite psilocin [Passie *et al*. 2002; Tylš *et al*. 2014; McKenna and Riba, 2016].

DMT and psilocybin are pharmacologically related to the ergoline D-lysergic acid diethylamide (LSD or LSD-25), a semisynthetic derivative of the naturally occurring lysergic acid moiety, present in several alkaloids found in the rye ergot fungus (*Claviceps purpurea*) [Hofmann, 2005; Passie *et al*. 2008; Hintzen and Passie, 2010; Smith *et al*. 2014; McKenna and Riba, 2016]. LSD was first synthetized by Albert Hofmann in 1938, and its psychoactive effects were discovered when the Swiss chemist accidentally ingested the drug in 1943 [Hofmann, 2005; Passie *et al*. 2008; Hintzen and Passie, 2010; Smith *et al*. 2014; McKenna and Riba, 2016].

DMT, psilocybin and LSD are agonists of serotonin 5-HT$_{1A/2A/2C}$ receptors [Pierce and Peroutka, 1989; McKenna *et al*. 1990; Glennon *et al*. 2000; Passie *et al*. 2002, 2008; Nichols, 2004; Hintzen and Passie, 2010; Hanks and González-Maeso, 2013; Tylš *et al*. 2014; Halberstadt, 2015]. Although the 5-HT$_{1A/2C}$ receptors modulate the effects of serotonergic hallucinogens, activation of fronto-cortical glutamate receptors secondary to 5-HT$_{2A}$ receptor-related glutamate release appears to be the key mechanism of action of these drugs [Nichols, 2004; González-Maeso *et al*. 2008; Moreno *et al*. 2011, 2013; Hanks and GonzálezMaeso, 2013; Santini *et al*. 2014; Buchborn *et al*. 2015; Carbonaro *et al*. 2015; Halberstadt, 2015]. The 5-HT$_{2A}$ and the metabotropic glutamate 2/3 (mGluR2/3) receptors show an overlapping distribution in the brain cortex, and their interaction has a crucial role in the neuropsychopharmacology of classical hallucinogens [González-Maeso *et al*. 2008; Moreno *et al*. 2011].

In the last 25 years, the ritual and therapeutic use of ayahuasca has spread from small cities in the Amazonian jungle to the urban centers of South America, the United States, Europe, Asia and Africa [Labate *et al*. 2009; Labate and Jungaberle, 2011; Labate and Cavnar, 2014]. Animal research [Glick *et al*. 1994; Aricioglu-Kartal *et* *al*. 2003; Hilber and Chapillon, 2005; Farzin and Mansouri, 2006; Lima *et al*. 2006; Wu *et al*. 2009; Fortunato *et al*. 2009, 2010a, 2010b; Réus *et al*. 2010, 2012; Brierley and Davidson, 2012, 2013; Liester and Prickett, 2012; Owaisat *et al*. 2012; Abelaira *et al*. 2013; Oliveira-Lima *et al*. 2015; Pic-Taylor *et al*. 2015; dos Santos *et al*. 2016] and observational and preliminary experimental studies of ayahuasca consumers [Grob *et al*. 1996; Barbosa *et al*. 2005, 2012; da Silveira *et al*. 2005; Doering-Silveira *et al*. 2005; dos Santos *et al*. 2007, 2016; Halpern *et al*. 2008; Barbosa *et al*. 2009; Labate *et al*. 2009, 2014; Fábregas *et al*. 2010; Labate and Jungaberle, 2011; Bouso *et al*. 2012; dos Santos, 2013; Thomas *et al*. 2013; Bouso and Riba, 2014; Fernández and Fábregas, 2014; Fernández *et al*. 2014; Loizaga-Velder and Loizaga Pazzi, 2014; Loizaga-Velder and Verres, 2014; Palhano-Fontes *et al*. 2014; Winkelman, 2014] suggest that ayahuasca and its isolated alkaloids have antidepressive, anxiolytic, and antiaddictive effects.

Moreover, experimental studies of acute ayahuasca administration to healthy volunteers [Riba *et al*. 2001, 2003, 2006; dos Santos *et al*. 2011, 2012; de Araujo *et al*. 2012; Palhano-Fontes *et al*. 2015; McKenna and Riba, 2016] and mental health assessments of long-term ayahuasca consumers [Grob *et al*. 1996; Barbosa *et al*. 2005, 2009, 2012; da Silveira *et al*. 2005; Doering-Silveira *et al*. 2005; Halpern *et al*. 2008; Fábregas *et al*. 2010; Bouso *et al*. 2012, 2015; dos Santos, 2013] suggest that this preparation is quite safe.

In the case of psilocybin and LSD between the mid-1950s and mid-1970s, several studies investigated the potential therapeutic use of these drugs in the treatment of neurosis, obsessive-compulsive disorder (OCD), substance dependence, and as an adjunctive therapy in the terminally ill [Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Grispoon and Bakalar, 1981; Riedlinger and Riedlinger, 1994; Abraham *et al*. 1996; Delgado and Moreno, 1998; Grob, 1998; Grof, 2001; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Liester, 2014; Oram, 2014; Smith *et al*. 2014; Bogenschutz and Johnson, 2016].

However, clinical research with hallucinogens was interrupted in the late 1960s mid-1970s due to an increase in the recreational use of these substances and their association with the countercultural movements [Grispoon and Bakalar, 1981; Riedlinger and Riedlinger, 1994; Grob, 1998; Grof, 2001; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Liester, 2014; Oram, 2014; Smith *et al*. 2014; Bogenschutz and Johnson, 2016]. Moreover, new rules for investigating novel pharmacological agents were introduced in the 1960-1970s [Liester, 2014; Oram, 2014], creating many difficulties for human hallucinogen research since most of these studies had important methodological limitations, such as absence of adequate control groups and follow-up measurements; substantial variation of dose and dosing duration among studies; lack of control for confounding factors such as pre-existing mental health problems or participant sex and age; non-standardized criteria for therapeutic outcome; and use of diverse theoretical approaches for assessing beneficial effects (ranging from psychoanalysis or transpersonal psychology to hypnosis and sensorial isolation or overload) [Grispoon and Bakalar, 1981; Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Riedlinger and Riedlinger, 1994; Grob, 1998; Grof, 2001; Dyck, 2006; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Liester, 2014; Oram, 2014; Bogenschutz and Johnson, 2016].

Therefore, although the early clinical studies with hallucinogens showed promising results, their methodological limitations suggest caution when interpreting their results. After a halt of almost 20 years, controlled laboratory studies in humans involving the administration of hallucinogens resumed in the 1990s with the investigations in healthy volunteers of Leo Hermle and collaborators in Germany, using orally administered mescaline [Hermle *et al*. 1992], and of Rick Strassman and coworkers in the United States, administering intravenous DMT [Strassman and Qualls, 1994; Strassman *et al*. 1994].

More recent preclinical research [Delgado and Moreno, 1998; Zghoul and Blier, 2003; Matsushima *et al*. 2009; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Buchborn *et al*. 2014; Bogenschutz and Johnson, 2016], case reports [Leonard and Rapoport, 1987; Riedlinger and Riedlinger, 1994; Hanes, 1996; Delgado and Moreno, 1998; Perrine, 1999; Wilcox, 2014] and observational [Krebs and Johansen, 2013; Hendricks *et al*. 2014, 2015; Johansen and Krebs, 2015] and preliminary experimental studies in healthy volunteers [Griffiths *et al*. 2006, 2011; Vollenweider and Kometer, 2010; Studerus *et al*. 2011; Kometer *et al*. 2012; Kraehenmann *et al*. 2016; Schmid *et al*. 2016] suggest that classical hallucinogens such as psilocybin and LSD have anxiolytic, antidepressive, and antiaddictive properties.

Moreover, early clinical research [Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Grispoon and Bakalar, 1981; Strassman, 1984; Riedlinger and Riedlinger, 1994; Grob, 1998; Grof, 2001; Passie *et al*. 2002, 2008; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Liester, 2014; Smith *et al*. 2014; Tylš *et al*. 2014; Bogenschutz and Johnson, 2016], and more recent observational studies [Krebs and Johansen, 2013; Hendricks *et al*. 2014, 2015; Johansen and Krebs, 2015], drug harm or risk assessments [Nutt *et al*. 2010; van Amsterdam *et al*. 2011, 2013, 2015; Morgan *et al*. 2013], and pharmacological studies of acute drug administration to healthy volunteers [Griffiths *et al*. 2006, 2011; Vollenweider and Kometer, 2010; Studerus *et al*. 2011; Kometer *et al*. 2012; Carhart-Harris *et al*. 2012a, 2012b, 2013; Kraehenmann *et al*. 2016; Schmid *et al*. 2016] suggest that these compounds have low toxicity and are reasonably safe when administered in supervised or controlled settings. Indeed, classic hallucinogens such as psilocybin and LSD are considered less toxic and harmful than most licit and illicit drugs [Nutt *et al*. 2010; van Amsterdam *et al*. 2011, 2013, 2015; Morgan *et al*. 2013].

Thus, considering this context, this study aimed to conduct a systematic literature review of clinical trials published in the last 25 years (1990- 2015) that investigated anxiolytic, antidepressive, and antiaddictive effects of ayahuasca, psilocybin and LSD.

Methods

Data for this systematic review were collected in accordance with the Systematic Reviews and Meta-Analyses guidelines (PRISMA) [Moher *et al*. 2009].

Data acquisition

We intended to identify all clinical trials available for review from 1 January 1990 to 1 July 2015, in which the anxiolytic, antidepressive, or antiaddictive effects of ayahuasca, psilocybin or LSD were analyzed.

Search strategy

Electronic searches were performed using the PubMed (1 January 1990 - 1 July 2015), LILACS (1 January 1990 - 1 July 2015) and SciELO (1 January 1990 - 1 July 2015) databases. The following key words were used: ayahuasca OR psilocybin OR lysergic acid diethylamide AND anxiety OR depression OR dependence. References were retrieved through searching electronic databases and manual searches through reference lists of identified literature. All studies published in English, Spanish, and Portuguese up to 1 July 2015 were included.

Eligibility criteria

The following inclusion and exclusion criteria were established prior to the literature search:

Article type

For purposes of this review, only clinical trials (open-label pilot studies, single-blind trials, or double-blind placebo-controlled trials) published in peer-reviewed journals were included. Animal studies, experimental studies in healthy volunteers, observational studies, review papers, qualitative studies, opinion pieces or comments, letters or editorials, conference abstracts or posters, books or book chapters, case reports, and published abstracts were excluded.

Study design

The review included only clinical trials involving patients with a diagnosis of an anxiety, depressive, or dependence disorder based on a structured diagnostic interview [Diagnostic and Statistical Manual of Mental Disorders (DSM)].

Participants

Only studies that included patients with a diagnosis of an anxiety, depressive, or dependence disorder based on a structured diagnostic interview (DSM) were included.

Interventions

All clinical trials evaluating the effects of ayahuasca, psilocybin, or LSD on anxiety, depressive, or dependence symptoms were included.

Comparisons

The main comparators considered were placebo and active placebo.

Outcomes

Reductions in anxiety, depressive, or dependence symptoms measured with validated scales.

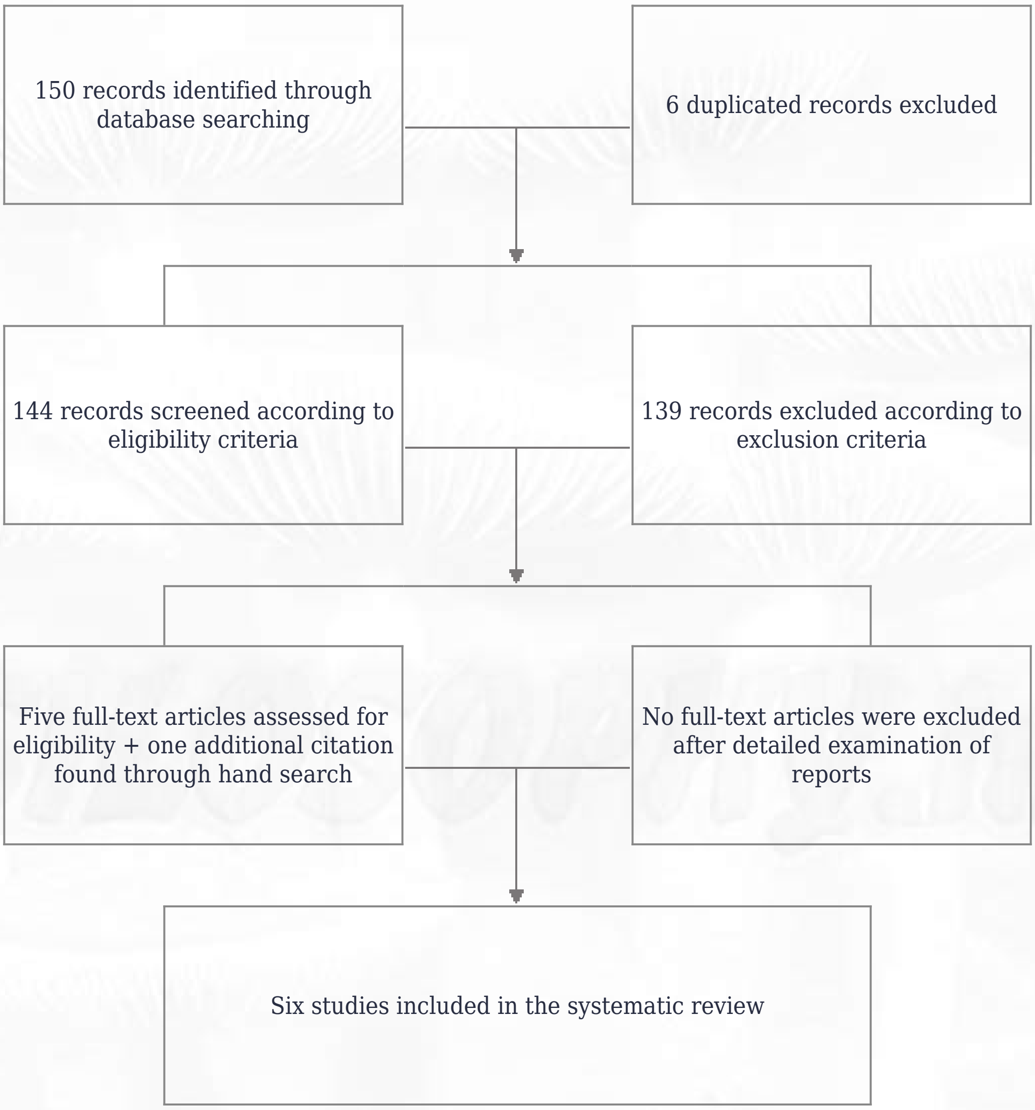
Data extraction

All studies were screened by two independent reviewers, with discrepancies resolved by a third reviewer. From the articles included we recorded names of authors, year of publication, study design (open label, single or double blind), characteristics of the participants (anxiety, depressive, or dependence symptoms, and sample size), response criteria (anxiolytic, antidepressive, or antiaddictive effect), type of intervention (drug, dose, and form of administration), and type of outcome measure (anxiety, depression, or dependence symptoms and scales).

Results

Study selection

A flow diagram illustrating the different phases of the systematic review is presented in Figure 1.



150 records identified through database searching
6 duplicated records excluded
144 records screened according to eligibility criteria
139 records excluded according to exclusion criteria
Five full-text articles assessed for eligibility + one additional citation found through hand search
No full-text articles were excluded after detailed examination of reports
Six studies included in the systematic review

Figure 1. Flow diagram illustrating the different phases of the systematic review.

The search of the literature yielded 150 separate references. Owing to the overlap of coverage between the databases, six of the references were found to be duplicates. Thus, a total of 144 citations were reviewed for abstract screening (first pass). Following the first pass, five potentially relevant references were identified [Moreno *et al*. 2006; Grob *et al*. 2011; Gasser *et al*. 2014; Bogenschutz *et al*. 2015; Osório *et al*. 2015]. The remaining 139 studies were excluded according to the exclusion criteria. Full-text reports of the five selected citations were obtained for more detailed evaluation (second pass). Following detailed examination of the reports, all five citations were included. Another citation was found after hand search of the bibliography of the selected reports [Johnson *et al*. 2014]. Thus, six citations were included in the systematic review.

Studies were classified according to drug (ayahuasca, psilocybin, or LSD) and symptom (anxiety, depression, or dependence symptoms). The included studies comprised four studies with psilocybin (one study of OCD: Moreno *et al*. 2006; one study of anxiety associated with advanced-stage cancer: Grob *et al*. 2011; one study of tobacco dependence: Johnson *et al*. 2014; and one study of alcohol dependence: Bogenschutz *et al*. 2015), one study with LSD (anxiety associated with life-threatening diseases: Gasser *et al*. 2014), and one study with ayahuasca [Osório *et al*. 2015]. The details of the selected studies are summarized in Table 1.

Despite the small number of studies, the small sample sizes (6-15 volunteers), the high degree of heterogeneity among studies, and the lack of placebo and control groups in three of the selected citations (open-label, proof-of-concept studies), the reported results consistently show that ayahuasca, psilocybin, and LSD have anxiolytic, antidepressive, and antiaddictive properties. These findings will be further discussed in detail below.

Table 1. Clinical trials assessing the anxiolytic, antidepressive, and antiaddictive effects of ayahuasca, psilocybin, and lysergic acid diethylamide (LSD).

Reference	No. of Patients/Diagnostic	Study Design	Drug (mg/kg)	Main Findings
Moreno *et al*. [2006]	9 OCD	Double blind, randomized, dose escalation	Psilocybin 0.25-0.3	Reduction in YBOCS scores in all subjects during one or more sessions Reduction in VAS scores for overall OCD symptom severity
Grob *et al*. [2011]	12 Anxiety associated with advanced-stage cancer	Double blind, randomized, active placebo (niacin 250 mg)	Psilocybin 0.2	Reduction in STAI trait anxiety scores at 1 and 3-month follow up, and in BDI scores at 6-month follow up
Gasser *et al*. [2014]	12 Anxiety associated with life-threatening diseases	Double blind, randomized, active placebo (LSD 20 μg)	LSD 2.9×10^{-3}	Reduction in STAI state anxiety scores at 2-month follow up
Johnson *et al*. [2014]	15 Tobacco dependence	Open label	Psilocybin 0.29-0.43	Reduction in breath CO levels, urine cotinine, daily smoking (TLFB), withdrawal (WSWS), craving (QSU), and temptation to smoke (SASE), and increase in confidence to abstain (SASE) through the 6-month follow up
Bogenschutz *et al*. [2015]	10 Alcohol dependence	Open label	Psilocybin 0.3-0.4	Reduction in percent-drinking days (TLFB) at all follow up points (weeks 5-36) Reduction in drinking consequences (SIP) and craving (PACS), and improves in self-efficacy (AASE), motivation (SOCRATES 8A), and mood (POMS) at multiple time points (weeks 5-36)
Osório *et al*. [2015]	6 MDD	Open label	Ayahuasca 2.2 ml/kg[1]	Reduction in HAM-D, MADRS, and BPRS-AD scores between baseline and 1, 7 and 21 days after drug intake

AASE, Alcohol Abstinence Self-Efficacy Confidence score; BPRS-AD, Anxious-Depression subscale of the Brief Psychiatric Rating Scale; BDI, Beck Depression Inventory; CO, carbon monoxide; DSM, Diagnostic and Statistical Manual of Mental Disorders; HAM-D, Hamilton Rating Scale for Depression; LSD, lysergic acid diethylamide; MADRS, Montgomery-Åsberg Depression Rating Scale; MDD, major depressive disorder; OCD, obsessive-compulsive disorder; PACS, Penn Alcohol Craving Scale; POMS, Profile of Mood States; QSU, Questionnaire on Smoking Urges; SASE, Smoking Abstinence Self-Efficacy scale; SIP, Short Inventory of Problems; SOCRATES 8A, Stages of Change Readiness and Treatment Eagerness Scale; STAI, State-Trait Anxiety Inventory; TLFB, Time-Line Follow-Back; VAS, Visual Analog Scales; WSWS, Wisconsin Smoking Withdrawal Scale; YBOCS, Yale-Brown Obsessive-Compulsive Scale.

[1] Orally administered as a decoction; alkaloid content 0.8 mg/ml DMT, 0.21 mg/ml harmine (no harmaline was detected).

Drugs

Psilocybin

Obsessive-compulsive disorder

In a double-blind study, nine subjects (seven men, two women) with obsessive-compulsive disorder (OCD) and at least one treatment failure with a serotonin reuptake inhibitor (mean 3.4 ± 1.9 treatment failures) received up to four different doses of orally administered psilocybin (one dose for test session) in a dose-escalation blinded design [Moreno *et al*. 2006]. Low (100 µg/kg), medium (200 µg/kg), and high (300 µg/kg) doses of psilocybin were administered in that order, and a very low dose (25 µg/kg) was inserted randomly and in double-blind design at any time after the first dose (100 µg/kg). Subjects met DSM-IV criteria for OCD and had a mean baseline Yale-Brown Obsessive-Compulsive Scale (YBOCS) score of 24.1 ± 5.9. YBOCS and Visual Analog Scales (VAS) scores for overall OCD symptom severity were measured immediately before drug ingestion and at 4, 8, and 24 hours after ingestion.

All subjects received the low dose, seven received the very low and medium doses, and six received all doses. Reductions in YBOCS scores ranging from 23% to 100% were observed in all subjects during one or more sessions. Moreover, 88.9% of subjects maintained no less than a 25% decrease and 66.7% maintained no less than a 50% decrease in YBOCS scores at 24 hours with at least one psilocybin dose. Symptom improvement during the following week was reported by two subjects, and one volunteer reported improvement at the 6-month follow up. VAS scores were also reduced throughout the study period, and psilocybin was well tolerated by all volunteers.

Anxiety associated with advanced-stage cancer

A double blind, randomized, placebo-controlled study assessed the safety and potential therapeutic effects of psilocybin in the treatment of psychological distress associated with the existential crisis of terminal disease [Grob *et al*. 2011]. Twelve subjects (11 women) with advanced-stage cancer and a DSM-IV diagnosis of acute stress disorder, generalized anxiety disorder, anxiety disorder due to cancer, or adjustment disorder with anxiety, received oral psilocybin (0.2 mg/kg) or the active placebo niacin (250 mg) in a double-blind fashion. The Beck Depression Inventory (BDI), the Profile of Mood States (POMS), and the State-Trait Anxiety Inventory (STAI) were administered the day before, at the conclusion, the day after, and 2 weeks after each experimental session. The BDI, POMS, and STAI were administered again at monthly intervals for 6 months after the final session.

All 12 participants completed the 3 months of follow up, 11 completed the 4-month follow up, and eight completed the 6-month follow up. During the study, two subjects died of their cancer and two became too ill to continue the study. Significant decreases were observed in STAI scores at the 1- and 3-month follow ups, and in BDI scores at the 6-month follow up. No significant changes were observed in POMS scores, and psilocybin was well tolerated by all patients. By the time of the paper's submission in 2010, 10 of the 12 subjects had died of their cancer.

Tobacco dependence

An open-label study assessed the effects of moderate (20 mg/70 kg) and high (30 mg/70 kg) doses of psilocybin in 15 (ten men, five women; mean age of 51 years) nicotine-dependent smokers [Johnson *et al*. 2014]. Participants had a mean of six previous lifetime quit attempts, and smoked a mean of 19 cigarettes per day for a mean of 31 years. Volunteers participated in a 15-week smoking cessation treatment (cognitive behavioral therapy), with psilocybin administration occurring in weeks 5 (moderate dose), 7 (high dose), and 13 (high dose) (participants were permitted to repeat the moderate dose on sessions two and three). Changes in mean cigarettes per day were compared between the 30 days prior to study intake and the 6 months after the first psilocybin session (at week 5 of treatment). Exhaled carbon monoxide (CO) and urinary cotinine level were assessed at intake, weekly throughout the intervention, and at 6-month follow up to measure recent smoking.

All participants completed the study. According to the Time-Line Follow-Back (TLFB) and biomarker data (breath CO, urine cotinine), 80% (12 of 15) of participants were abstinent at 6-month follow up. Among the entire sample, significant reductions from intake to the 6-month follow up were observed in breath CO levels, urine cotinine, and self-reported daily smoking. Moreover, craving [Questionnaire on Smoking Urges (QSU)] and temptation to smoke [Smoking Abstinence Self-Efficacy scale (SASE)] were significantly reduced across all time points.

Significant increases were reported for confidence to abstain (SASE) from intake to the 6-month follow up, and withdrawal scores [Wisconsin Smoking Withdrawal Scale (WSWS)] peaked at 1-week post-psilocybin and decreased significantly through the 6-month follow up. No significant adverse events were reported during psilocybin sessions.

Alcohol dependence

Ten volunteers (four women, six men) with DSM-IV alcohol dependence (mean duration of dependence 15.1 ± 11.5 years, range 4-32) participated in an open-label trial that included a 12-session psychosocial intervention and two oral doses of psilocybin [Bogenschutz *et al*. 2015]. Eight of the 10 volunteers had evidence of physical dependence (tolerance or withdrawal). The psychosocial intervention included seven sessions of Motivational Enhancement Therapy (MET); three preparation sessions; two debriefing sessions; four sessions before the first psilocybin dose (0.3 mg/kg); four sessions between the first and second psilocybin dose (0.4 mg/kg); and four sessions after the second psilocybin dose. Outcome measures were collected for 36 weeks.

Nine volunteers completed all follow-up assessments; 10 completed the first psilocybin session, and seven the second session. However, only six patients were included in the analysis of the second session since one volunteer did not receive the 0.4 mg/kg psilocybin dose, receiving the 0.3 mg/kg due to meeting criteria for 'complete mystical experience' [Mystical Experience Questionnaire (MEQ)] in the first session. One patient discontinued participation and was excluded from the analysis.

According to the TLFB, percent-drinking days (consumption of any amount of an alcoholic beverage) and heavy-drinking days (consumption of four or more drinks of 14 g of alcohol) decreased significantly relative to weeks 1-4 prior to psilocybin, and also during weeks 5-12 relative to baseline. Following the first psilocybin session, percent-drinking days and heavy-drinking days were significantly lower than baseline at all follow-up points.

Significant correlations were observed between the overall intensity (Hallucinogen Rating Scale Intensity score; Altered States of Consciousness Scale summary score) and mystical quality (MEQ) of the psilocybin session and changes in percent-drinking days (TLFB), craving [Penn Alcohol Craving Scale (PACS)], self-efficacy to abstain from drinking [Alcohol Abstinence Self-Efficacy Confidence score (AASE)], and motivation [Stages of Change Readiness and Treatment Eagerness Scale (SOCRATES 8A)].

Improvements were largely maintained throughout the 36 weeks follow up. At multiple time points relative to baseline and (or) week 4, psilocybin reduced drinking consequences [Short Inventory of Problems, (SIP); weeks 8 to 36] and craving (PACS), and improved self-efficacy (AASE; weeks 5, 9, 24 and 36), motivation (SOCRATES 8A; weeks 5 to 36), and mood [Profile of Mood States, (POMS); weeks 4 and 24]. No significant adverse effects were reported after psilocybin administration.

Lysergic acid diethylamide (LSD)

Anxiety associated with life-threatening diseases

A double blind, randomized, active placebo-controlled study assessed the effects of lysergic acid diethylamide (LSD) in 12 patients (seven men, four women) with anxiety associated with life-threatening diseases (cancer, or chronic motor or inflammatory diseases) [Gasser *et al*. 2014]. Volunteers had a score of no less than 40 on the state or trait scales of the STAI and a DSM-IV diagnosis of major depressive disorder (MDD), reactive depression, dysthymia, posttraumatic stress disorder (PTSD), panic disorder, or social phobia. The study included drug-free psychotherapy sessions and two LSD-assisted psychotherapy sessions. Volunteers received either an experimental dose (200 µg, *n* = 8) or an active placebo (20 µg, *n* = 3) of LSD 2 to 3 weeks apart, with an open-label crossover to 200 µg of LSD after the initial blinded treatment (*n* = 4). Outcome data were collected at baseline, 1 week after LSD sessions, and at 2- and 12-month follow ups.

At the 2-month point, STAI state anxiety was significantly reduced, and a trend was found for reductions in STAI trait anxiety. STAI reductions were sustained for 12 months. Beneficial results were also observed in secondary outcome measures, including the European Cancer Quality of Life Questionnaire 30-item version 1.0 (EORTCQLQ-30), the Symptom Checklist-90-Revised (SCL-90-R), and the Hospital Anxiety and Depression Scale (HADS). However, due to concerns about multiplicity, changes in secondary outcome measures were not analyzed for statistical significance. No adverse effects or treatment-related serious adverse events were reported.

Ayahuasca

Major depressive disorder

An open-label trial assessed the antidepressive potential of ayahuasca in patients with diagnosis of recurrent major depressive disorder (MDD) [Osório *et al*. 2015]. A single dose of orally administered ayahuasca (2.2 ml/kg body weight) was administered to six volunteers (two men, four women) suffering a mild (*n* = 2), moderate (*n* = 3) or severe (*n* = 1) depressive episode. Ayahuasca administration produced statistically significant reductions of up to 82% in depressive scores between baseline and 1, 7 and 21 days after drug intake, according to the Hamilton Rating Scale for Depression (HAMD), the Montgomery-Åsberg Depression Rating Scale (MADRS), and the Anxious-Depression subscale of the Brief Psychiatric Rating Scale (BPRS). Ayahuasca did not produce significant effects in the Young Mania Rating Scale (YMRS) scores or in the other subscales of the BPRS. Ayahuasca was well tolerated by all patients and vomiting was the only adverse effect recorded, being reported by 50% of the volunteers. Patients did not consider this emetic effect as causing severe discomfort.

Discussion

Possible mechanisms of therapeutic action

The mechanisms of action responsible for the beneficial effects produced by ayahuasca, psilocybin and LSD are not completely understood. Preclinical evidence show that ayahuasca [Lima *et al*. 2006; Pic-Taylor *et al*. 2015] and its β-carbolines harmine [Aricioglu-Kartal *et al*. 2003; Farzin and Mansouri, 2006; Fortunato *et al*. 2009, 2010a, 2010b; Réus *et al*. 2010, 2012; Brierley and Davidson, 2012; Owaisat *et al*. 2012] and harmaline [Glick *et al*. 1994; Hilber and Chapillon, 2005; Wu *et al*. 2009], as well as psilocybin [Matsushima *et al*. 2009] and LSD [Zghoul and Blier, 2003; Buchborn *et al*. 2014], have antidepressive, anxiolytic, and antiaddictive properties. Experimental studies with healthy volunteers report that acute administration of DMT [Gillin *et al*. 1976; Strassman *et al*. 1994; Riba *et al*. 2015], psilocybin [Griffiths *et al*. 2006, 2011; Studerus *et al*. 2011; Kometer *et al*. 2012; Kraehenmann *et al*. 2016], and LSD [Schmid *et al*. 2016] increase positive mood. Furthermore, observational and preliminary experimental studies of ayahuasca consumers [Grob *et al*. 1996; Barbosa *et al*. 2005, 2009, 2012; da Silveira *et al*. 2005; Doering-Silveira *et al*. 2005; dos Santos *et al*. 2007, 2016; Halpern *et al*. 2008; Labate *et al*. 2009, 2014; Fábregas *et al*. 2010; Labate and Jungaberle, 2011; Bouso *et al*. 2012; dos Santos, 2013; Thomas *et al*. 2013; Bouso and Riba, 2014; Fernández and Fábregas, 2014; Fernández *et al*. 2014; Loizaga-Velder and Loizaga Pazzi, 2014; Loizaga-Velder and Verres, 2014; Palhano-Fontes *et al*. 2014; Winkelman, 2014], as well as case reports [Leonard and Rapoport, 1987; Riedlinger and Riedlinger, 1994; Hanes, 1996; Delgado and Moreno, 1998; Perrine, 1999; Wilcox, 2014] and observational studies [Krebs and Johansen, 2013; Hendricks *et al*. 2014, 2015; Johansen and Krebs, 2015] involving psilocybin and LSD, also suggest that these drugs have therapeutic potentials.

Since DMT, psilocybin and LSD are agonists of serotonin 5-HT$_{1A/2A/2C}$ receptors [Pierce and Peroutka, 1989; McKenna *et al*. 1990; Glennon *et al*. 2000; Passie *et al*. 2002, 2008; Nichols, 2004; Hintzen and Passie, 2010; Hanks and González-Maeso, 2013; Tylš *et al*. 2014; Halberstadt, 2015], these receptors may be involved in the therapeutic effects of these tryptamines. In fact, cortical expression of 5-HT$_{1A/2A/2C}$ receptor is altered in postmortem samples of depressed patients, suggesting that these receptors are involved in emotional processing [Vollenweider and Kometer, 2010; Baumeister *et al*. 2014]. Furthermore, animal models and clinical studies show that 5-HT$_{1A}$ receptor agonists have anxiolytic and antidepressive properties [Nutt, 2005; Katzman, 2009; Baumeister *et al*. 2014], and 5-HT$_{2A/2C}$ receptor agonists reduce anxiety- and depression-related behavior in animals [Masuda and Sugiyama, 2000; Nic Dhonnchadha *et al*. 2003a, 2003b; Baumeister *et al*. 2014].

Another possible mechanism of therapeutic action is the modulation of glutamatergic neurotransmission induced by 5-HT$_{2A}$-receptor agonism [Nichols, 2004; González-Maeso *et al*. 2008; Vollenweider and Kometer, 2010; Moreno *et al*. 2011, 2013; Hanks and González-Maeso, 2013; Santini *et al*. 2014; Buchborn *et al*. 2015; Carbonaro *et al*. 2015; Halberstadt, 2015]. Activation of frontocortical glutamate networks by 5-HT$_{2A}$ receptor agonists could lead to increases in the expression of neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and glial cell line-derived neurotrophic factor (GDNF) and in the size of dendritic spines on cortical neurons, thus enhancing neuroplasticity and neurogenesis [Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Ross, 2012; Baumeister *et al*. 2014; Bogenschutz and Johnson, 2016]. For instance, depression is associated with deficient neurogenesis and neurotrophic activity, and BDNF levels are decreased in depressed patients and normalized after antidepressant treatment [Baumeister *et al*. 2014]. Furthermore, alcohol self-administration and conditioned place preference are inversely related to BDNF or GDNF expression in animal models [Bogenschutz and Pommy, 2012; Bogenschutz and Johnson, 2016]. Interestingly, a low dose (0.1 mg/kg) of psilocybin produced a trend toward increased neurogenesis in the mouse hippocampus 2 weeks after its administration, while a high dose (1 mg/kg) significantly decreased neurogenesis [Catlow *et al*. 2013]. These results suggest that the effects of psilocybin on neurogenesis are dose- and time-related.

Agonism at the 5-HT$_{2A}$ receptor could also produce beneficial effects due to an anti-inflammatory action [Nau *et al*. 2013; Baumeister *et al*. 2014; dos Santos, 2014; Szabo *et al*. 2014]. Increased levels of pro-inflammatory cytokines such as tumor necrosis factor α (TNFα), interleukin-6 (IL-6), IL-8, and IL-1β are associated with depressive illness, while normalization of these levels are related to antidepressant effects [Baumeister *et al*. 2014; Réus *et al*. 2015]. The 5-HT$_{2A}$ receptor is expressed in central and peripheral immune-related cells [Stefulj *et al*. 2000; Nau *et al*. 2013], and 5-HT$_{2A}$ agonists may modulate the immune system [Forrer and Goldner, 1951; Feld *et al*. 1958; Sackler *et al*. 1963, 1966; Hollister and Sjoberg, 1964; House *et al*. 1994, 1997; Stefulj *et al*. 2000; Passie *et al*. 2002; Davydova *et al*. 2010; Hintzen and Passie, 2010; dos Santos *et al*. 2011, 2012; Frecska *et al*. 2013; Nau *et al*. 2013; Baumeister *et al*. 2014; dos Santos, 2014; Szabo *et al*. 2014]. Indeed, in vitro studies show that LSD inhibits the production of IL-6 [House *et al*. 1994, 1997], and the serotonergic hallucinogen 4-iodo-2,5-dimethoxyphenylisopropylamine (DOI, a 5-HT$_{2A}$ receptor agonist) produces anti-inflammatory effects in mice by blocking TNF-α-induced expression of pro-inflammatory cell adhesion (Icam-1, Vcam-1), cytokine (IL-6, IL-1β), and chemokine (Mcp-1, Cx3cl1) genes, and expression of VCAM-1 protein [Nau *et al*. 2013]. These effects were blocked by a 5-HT$_{2A}$ selective antagonist, implicating this receptor in the anti-inflammatory effects of DOI. Moreover, DMT and the related tryptamine 5-methoxy-DMT (5-MeO-DMT) reduced the mRNA expression and the levels of IL-6, IL-8, IL-1β, and TNF-α, increased the levels of the anti-inflammatory cytokine IL-10, and inhibited the immune responses of inflammatory T helper 1/17 (Th1/Th17) cells [Szabo *et al*. 2014]. Interestingly, gene knock-down experiments showed that the effects of both tryptamines on TNFα, IL-10, and Th1/Th17 responses were mediated by the sigma-1 receptor, and recent studies show that DMT is an endogenous agonist for the sigma-1 receptor [Fontanilla *et al*. 2009; Su *et al*. 2009; Frecska *et al*. 2013; Szabo *et al*. 2014].

The possible modulation of the sigma-1 receptor by DMT shows that other mechanisms of action that are not dependent of the 5-HT$_{1A/2A/2C}$ receptors may also be involved in the therapeutic action of classic hallucinogens. For instance, harmine, THH and harmaline reversibly inhibit MAO-A [Buckholtz and Boggan, 1977; McKenna *et al*. 1984; Ott, 1994, 1999, 2004; Riba *et al*. 2001, 2003; McKenna and Riba, 2016], and reversible inhibitors of MAO-A (RIMAs) are clinically used as anxiolytic and antidepressant drugs [Yamada and Yasuhara, 2004; Nutt, 2005]. Moreover, rodent studies show that the antidepressive effects of harmine are associated with increases in BDNF levels [Fortunato *et al*. 2009; 2010a; 2010b].

Neural oxidative stress and subsequent neuroinflammation are associated with psychiatric disorders such as depression [Réus *et al*. 2015], and several preclinical studies show that harmine and harmaline have antioxidant and neuroprotective effects that seem to be mediated by MAO inhibition [Maher and Davis, 1996; Biradar *et al*. 2013], regulation of the dual specificity tyrosine-phosphorylation-regulated kinase DYRK1A [Frost *et al*. 2011], modulation of dopaminergic [Lee *et al*. 2000; Schwarz *et al*. 2003], cholinergic [Biradar *et al*. 2013], and glutamatergic [Maher and Davis, 1996; Li *et al*. 2011; Sun *et al*. 2014] pathways, interaction with voltage-gated membrane channels [Splettstoesser *et al*. 2005], and regulation of cell-energy homeostasis, mitochondrial functions, and oxygen free radical scavenging [Moura *et al*. 2007; Réus *et al*. 2010, 2012; Abelaira *et al*. 2013]. Furthermore, harmine also has anti-inflammatory properties that seem to be mediated at least in part by DYRK1A [Khor *et al*. 2015].

The antiaddictive effects of ayahuasca, psilocybin and LSD could also be related to the activation of the dopaminergic system. For instance, preclinical studies show that LSD [Nichols, 2004; Passie *et al*. 2008; Hintzen and Passie, 2010], psilocybin [Tylš *et al*. 2014; Sakashita *et al*. 2015], and ayahuasca [de Castro-Neto *et al*. 2013] may indirectly stimulate dopaminergic pathways, probably through 5-HT$_{2A}$-receptor activation (LSD, psilocybin, and DMT) or MAO inhibition (β-carbolines). Moreover, acute psilocybin administration indirectly increased (through 5-HT$_{1A/2A}$ receptors) the release of dopamine in the ventral striatum in humans [Vollenweider *et al*. 1999]. Animal studies suggest that the antiaddictive potentials of harmine and harmaline appear to involve imidazoline, glutamate, and dopamine pathways [Glick *et al*. 1994; Iurlo *et al*. 2001; Aricioglu-Kartal *et al*. 2003; Schwarz *et al*. 2003; Brierley and Davidson, 2012, 2013; Owaisat *et al*. 2012].

Recent neuroimaging studies in humans suggest that the mood-enhancing properties of ayahuasca and psilocybin could be related to modifications in the activity of brain regions such as the amygdala and the anterior cingulate cortex (ACC), involved in emotional processing, and the default mode network (DMN), a group of brain regions associated with introspection and other internally focused functions [Riba *et al*. 2006; Araujo *et al*. 2012; Carhart-Harris *et al*. 2012a, 2014; Tagliazucchi *et al*. 2014; Bouso *et al*. 2015; Palhano-Fontes *et al*. 2015; Alonso *et al*. 2015; Kraehenmann *et al*. 2016; McKenna and Riba, 2016]. Psilocybin reduced amygdala reactivity, which correlated with increases in positive mood [Kraehenmann *et al*. 2016]. Increased activity of the DMN is associated with intensification of the self-reference process of rumination, which is an important depressive symptom, and acute administration of ayahuasca [Palhano-Fontes *et al*. 2015] and psilocybin [Carhart-Harris *et al*. 2012a] reduces brain activity in key regions of the DMN, such as the posterior cingulate cortex (PCC). Moreover, regular ayahuasca use is associated with cortical thinning in the PCC [Bouso *et al*. 2015].

Early human research with classical hallucinogens suggests that the therapeutic properties of these compounds are related at least in part to their effects on perceptions, emotions, and thoughts [Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Grispoon and Bakalar, 1981; Riedlinger and Riedlinger, 1994; Abraham *et al*. 1996; Delgado and Moreno, 1998; Grob, 1998; Grof, 2001; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Liester, 2014; Oram, 2014; Majiæ *et al*. 2015; Bogenschutz and Johnson, 2016]. The subjective experience produced by these drugs would create a 'window of opportunity' in which changes in unhealthy thoughts, emotions, and behaviors could take place in a psychotherapeutic context [Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Grispoon and Bakalar, 1981; Riedlinger and Riedlinger, 1994; Abraham *et al*. 1996; Delgado and Moreno, 1998; Grob, 1998; Grof, 2001; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Liester, 2014; Oram, 2014; Majiæ *et al*. 2015; Bogenschutz and Johnson, 2016]. Recent neuroimaging studies with ayahuasca and psilocybin seem to corroborate these early ideas by suggesting that the altered state of consciousness produced by these drugs would create a disruption or interruption of the repetitive, rigid, and pathological pattern of negative and compulsive thoughts present in anxiety and mood disorders and in drug dependence, contributing to mental flexibility and changes in perspective, values, and behavior [Carhart-Harris *et al*. 2012a, 2014; Tagliazucchi *et al*. 2014; Palhano-Fontes *et al*. 2015; McKenna and Riba, 2016].

Furthermore, the ability of classical hallucinogens to elicit religious, mystical, transcendent, or peak experiences has also been proposed as a possible psychological mechanism associated with the beneficial effects of these drugs [Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Grispoon and Bakalar, 1981; Riedlinger and Riedlinger, 1994; Abraham *et al*. 1996; Delgado and Moreno, 1998; Grob, 1998; Grof, 2001; Hofmann, 2005; Dyck, 2006; Griffiths *et al*. 2006, 2008, 2011; Hintzen and Passie, 2010; Vollenweider and

Kometer, 2010; MacLean *et al*. 2011; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Liester, 2014; Oram, 2014; Majiæ *et al*. 2015; Bogenschutz and Johnson, 2016]. Indeed, recent studies in healthy individuals show that acute psilocybin administration induces highly meaningful and spiritually significant experiences with sustained positive changes in attitudes, mood, personality, and behavior [Griffiths *et al*. 2006, 2008, 2011; MacLean *et al*. 2011]. Moreover, a secondary analysis of the data from the study of psilocybin and tobacco dependence reported that the mystical-type effects of psilocybin and their personal meaning, spiritual significance, and impact on well-being were correlated with improvements in smoking cessation [Garcia-Romeu *et al*. 2014; Johnson *et al*. 2014]. A qualitative follow-up assessment of the patients enrolled in the study of LSD-assisted psychotherapy for anxiety associated with a life-threatening disease also suggested that the intense emotional experiences with mystic-like features produced by LSD could mediate the observed long-term beneficial changes in perspectives, attitudes, values, and quality of life [Gasser *et al*. 2014, 2015].

Interestingly, these findings are consistent with studies that suggest that the dissociative, psychotomimetic, and mystical-type effects produced by the *N*-methyl-D-aspartate (NMDA) antagonist ketamine may mediate the anxiolytic [Kolp *et al*. 2007], antidepressive [Sos *et al*. 2013; Luckenbaugh *et al*. 2014], and antiaddictive [Krupitsky *et al*. 1992, 2002, 2007; Krupitsky and Grinenko, 1997; Jansen, 2001; Kolp *et al*. 2006; Krupitsky and Kolp, 2007; Dakwar *et al*. 2014a, 2014b] properties of this non-classic hallucinogen. Moreover, some authors suggested that the temporary mental state produced by classic hallucinogens might induce profound long-term effects by producing an 'inverse post-traumatic stress disorder (PTSD)-like effect' in which a highly significant and positive experience would cause lasting beneficial changes, as opposed to chronic negative mood and other detrimental symptoms caused by a single traumatic event, which characterizes PTSD [MacLean *et al*. 2011; Young 2013; Garcia-Romeu *et al*. 2014].

Human hallucinogenic research performed in the 1960s and 1970s also suggests that the context and the psychotherapeutic approach used in combination with classic hallucinogens are also important components of the beneficial effects produced by these drugs [Kurland *et al*. 1971; McGlothlin and Arnold, 1971; Grispoon and Bakalar, 1981; Riedlinger and Riedlinger, 1994; Abraham *et al*. 1996; Delgado and Moreno, 1998; Grob, 1998; Grof, 2001; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Burdick and Adinoff, 2013; Baumeister *et al*. 2014; Liester, 2014; Oram, 2014; Majiæ *et al*. 2015; Bogenschutz and Johnson, 2016]. The methodology of the clinical trials included in the present systematic review are very diverse regarding this topic: three studies assessed the effects of single-dose exposures without psychotherapeutic approaches [Moreno *et al*. 2006; Grob *et al*. 2011; Osório *et al*. 2015] and three trials included some form of psychological intervention over a few weeks [Gasser *et al*. 2014; Johnson *et al*. 2014; Bogenschutz *et al*. 2015]. The studies without psychotherapy suggest that biochemical mechanisms may be involved in the beneficial effects observed. On the other hand, the inclusion of psychological interventions in the other studies suggests that at least some part of the therapeutic results is related to nondrug factors. Placebo effects and enhanced suggestibility may also play a role as adjuncts in hallucinogen-assisted psychotherapy [Young, 2013; Carhart-Harris *et al*. 2015].

Future research should investigate the possible influence of different psychotherapeutic approaches or other nondrug factors - such as patient preparation before drug administration and integration of the drug session afterwards - in mediating the therapeutic properties of classic hallucinogens.

Safety

No serious adverse reactions were reported in any of the clinical trials reviewed in the present systematic review, suggesting that classic hallucinogens can be safely administered to patients suffering anxiety, depression, or drug dependence. Previous experimental studies of acute ayahuasca administration to healthy volunteers [Riba *et al*. 2001, 2003, 2006; dos Santos *et al*. 2011, 2012; de Araujo *et al*. 2012; Palhano-Fontes *et al*. 2015; McKenna and Riba, 2016] also suggest that this drug can be safely administered in controlled experimental settings. Observational studies of long-term ayahuasca consumers [Grob *et al*. 1996; Barbosa *et al*. 2005, 2009, 2012; da Silveira *et al*. 2005; Doering-Silveira *et al*. 2005; Halpern *et al*. 2008; Fábregas *et al*. 2010; Bouso *et al*. 2012, 2015; dos Santos, 2013] also suggest that this brew has a low toxicity profile when consumed in ritual contexts. Previous clinical research [Kurland *et al*. 1971; McGlothlin and Arnold, 1971;

Grispoon and Bakalar, 1981; Strassman, 1984; Riedlinger and Riedlinger, 1994; Grob, 1998; Grof, 2001; Passie *et al*. 2002, 2008; Hofmann, 2005; Dyck, 2006; Hintzen and Passie, 2010; Vollenweider and Kometer, 2010; Bogenschutz and Pommy, 2012; Krebs and Johansen, 2012; Bogenschutz, 2013; Liester, 2014; Smith *et al*. 2014; Tylš *et al*. 2014; Bogenschutz and Johnson, 2016] and recent observational studies [Krebs and Johansen, 2013; Hendricks *et al*. 2014, 2015; Johansen and Krebs, 2015], drug harm or risk assessments [Nutt *et al*. 2010; van Amsterdam *et al*. 2011, 2013, 2015; Morgan *et al*. 2013], and experimental studies with healthy volunteers [Vollenweider and Kometer, 2010; Carhart-Harris *et al*. 2012a, 2012b, 2013] also suggest that psilocybin and LSD can be safely administered in controlled settings.

Limitations

A main limitation of the present systematic review is the inclusion of a small number of studies (six) with small sample sizes (6-15 volunteers), which limits the generalization of the reported results. Included studies also show a high degree of heterogeneity, and three of the selected citations did not include placebo or a control group (open-label, proof-of-concept studies). Another important limitation is the difficulty in disentangling placebo effects, drug effects, and the influence of the psychological intervention included in the clinical trial.

However, despite these important limitations, results consistently showed that ayahuasca, psilocybin, and LSD produced anxiolytic, antidepressive, and antiaddictive effects in patients, and these results were also observed in animal studies and with healthy volunteers. Given the low success rates of current pharmacological and nonpharmacological treatments for drug dependence and anxiety and mood disorders, and considering the high morbidity and mortality associated with these disorders, it is necessary to perform more studies with these drugs, even if only a small portion of patients may reduce their suffering with these drugs. Future studies should include more patients, placebo or active placebo, randomized and double-blind designs, and multiple doses during treatment. Moreover, the influence of psychological interventions and the possible increases in therapeutic efficacy proportionated by these psychotherapeutic approaches should be better explored.

Conclusion

Currently available pharmacological treatments for drug dependence and anxiety and mood disorders have limited efficacy and often produce important adverse reactions that may limit treatment continuation. Classic tryptamine hallucinogens such as ayahuasca/DMT, psilocybin, and LSD are safely administered in controlled settings and several basic, experimental, and clinical studies suggest that these drugs have anxiolytic, antidepressive, and antiaddictive effects. Such beneficial properties seem to be mediated by an agonist action of these compounds on 5-HT$_{1A/2A/2C}$ receptors, which are involved in emotional processing, regulation of neurotrophic factors, anti-inflammatory actions, and modulation of frontal and medial brain structures. Other mechanisms of action not related to serotonergic receptors, such as regulation of cell energy homeostasis, mitochondrial functions, and oxidative stress, also appear to mediate these therapeutic effects.

The reviewed studies suggest that the therapeutic use of classic hallucinogens may offer to some patients fast-acting and prolonged beneficial effects after a single dose, producing few adverse effects. Indeed, interest in the medicinal uses of this class of drugs is increasing: new clinical trials investigating the effects of psilocybin in the treatment of alcoholism, cocaine dependence, tobacco dependence, and anxiety and depression associated with cancer are currently underway [ClinicalTrials.gov identifiers: NCT02061293, NCT02037126, NCT01943994, NCT00957359, NCT00465595]. Moreover, our group recently replicated the results of the original open-label, proof-of-concept study [Osório *et al*. 2015] but including an increased sample size (n =17) and single-photon emission computed tomography (SPECT), showing that ayahuasca antidepressive properties may be associated with increased blood perfusion in brain areas related to depressive symptoms (Sanches *et al*. 2016 "This reference was not included in the review because it was not published at the time of the electronic search"). Our group is currently performing randomized, double blind, placebo-controlled studies assessing the antidepressive and anxiolytic potentials of ayahuasca [Frood, 2015].

Further studies are urgently needed to better understand the effects of classical tryptamine hallucinogens in psychiatric disorders.

Abstract

Death is our most repressed consciousness, it inheres our condition as the primordial fear. Perhaps it was necessary that this angst be repressed in man or he would be hurled against the dark forces of nature. Modern ethos was built on this edifice, where the 'denial of death' while 'embracing one's symbolic immortality' would be worshipped, so this ideology simply overturned and repressed looking into the morass of the inevitable when it finally announced itself. Once this slowly pieced its way into all of life, 'death' would soon become a terminology in medicine too and assert its position, by giving a push to those directly dealing with the dying to shy away from its emotional and spiritual affliction. The need to put off death and prolong one's life would become ever more urgent. Research using psychedelics on the terminally ill which had begun in the 1950s and 1960s would coerce into another realm and alter the face of medicine; but the aggression with which it forced itself in the 1960s would soon be politically maimed, and what remained would be sporadic outpours that trickled its way from European labs and underground boot camps. Now, with the curtain rising, the question has etched itself again, about the use of psychedelic drugs in medicine, particularly psychedelic psychotherapy with the terminally ill. This study is an attempt to philosophically explore death anxiety from its existential context and how something that is innate in our condition cannot be therapeutically cured. Psychedelic use was immutably linked with ancient cultures and only recently has it seen its scientific revival, from which a scientific culture grew around psychedelic therapy. How much of what was threaded in the ritual and spiritual mores can be extricated and be interpreted in our own mechanized language of medicine is the question that nudges many.

Key words: Death consciousness, LSD, psychedelic drugs, psychedelic therapy, terminally ill.

Introduction

Denial of the death consciousness
Our most primordial angst stems from the repression of our consciousness of death. Buddhism sends us this augury to a lost, perhaps reluctant vision. The dramatic illusion of self-consciousness rests in the way in which Buddhism deconstructs this pervious 'sense of self' as an interplay of the mental and the physical.[1] This primeval angst that was inherent in the human condition, had to be repressed in man or he would be lost in the vast openness of nature, of the unknowing.[2] It had to be shaped and grounded in a way so he could reconcile with his existence. By overcoming the fear of this repressed death angst, one in fact emerges as his own preserver and nourisher, interpreted as the "Oedipal project".[3] Buddhism situates this to the effort of the ideational "sense-of-self" at self-autonomy; the relentless pursuit of wanting to tame this conditioned consciousness, as the symbolic immortal.

Not being equipped to face the totality of his dual existence, one that had flowered as the birthing wound, and the other, more brutal repression of the inevitable - his imminent death; a duality birthed out of the same fear, paradoxically.[1] Right from the time when the birthing wound emerged as the 'conditioned consciousness' it had to cocoon its preservation, find meaning in existence, become real. With this his consciousness would come to being grounded, being ingrained in a reality of his own construct, in a world that he had himself envisaged, history's own doing entrenched in man's collective psyche, hurling him into the continuous spin of objectifying himself in the real world.[4]

But had he not secured this real world that he lived in, he would have been thrown into the abyss of non-being, a vacuum that would gnaw the core of his existence had he not reassured his place in the world. This underlies the Buddhist deconstruction of the ego's anxiety about its own 'sunyata'(emptiness) and its ignorance of the subject-object dualism. Rooted deeply in the Mahayana and Advaita Vedanta tradition, this primary sense of illusory split between the self and the world was because of ignorance.[1]

Kant in his 'first Critique', tried to show this fundamental flaw that underlies traditional metaphysics, "*the presupposition that substantive knowledge claims can be made about the world independently of experience*." He stabbed at the very heart of metaphysical ideology by claiming that, "*it is impossible to know anything a priori about the world as it is, independently of our cognitive apparatus*".[4] "*Though we can make certain synthetic a priori claims, these claims are not about reality per se, but only about reality as it is experienced by us. It is only because we posses certain cognitive principles enabling us to experience the world that we can make certain claims about the world as it appears*".[4] This fallacy was mooted right from the way we observe this objective reality as the other, as for this objectivity to remain consistent, each of us kept constructing reality in a way that it concealed from us the knowledge that we have constructed it. This can be seen in the way we experience reality, the way things appear to us, as though it were independent of our nature.[5]

Constructing an intelligible world

It was when Western civilization began to explode as the Renaissance, that it brought along a new wave of success, and with it isolation and despair.[1] This wave spilled over to the later centuries, sprouting along new seeds, of man's urgent craving for self eminence and notoriety, something that grounded a strong hold in his consciousness as an obscure craving for his own symbolic immortality.[1]

To secure this superfluous subjective self he had to keep holding onto the objective world, play his part, an inescapable act of self consciousness itself that had been endowed through his act of birth. This burden was not for him to bear alone, this had to be leveled with the social act of being itself, attempt itself in solidarity with his fellow human beings so it could be recompensed collectively. This ever repetitive act of man became sedimented in his collective consciousness from which there was no looking back.[5,6] This experiential self in the midst of his self constructed realism became the whole in which he began to grasp his truest capacity of being, often lived in bad faith, *mauvaise foi* as decreed by Sartre.[7] Man's view of himself became fixed and repetitive, determined by a collective madness that was beyond his control. It was this "*pretence of unfreedom that gave him more liberty to disown responsibility in good conscience*". [7] This trickles down to man's search for unity and meaning in his existence when there was none, because when there is a 'demand' for meaning instead of 'search' he knew that this demand was futile as it was made in the death of his historical and metaphysical ideologies.[7]

This awareness only gnawed despair, and the sense of its futility was to become ever more severe when one was dying. One was simply not prepared for this; the consciousness of separating from the self, from life had never seemed so real.

Modern ethos was built on the edifice in which the 'denial of death'[8] while 'embracing one's symbolic immortality' began to be worshipped, so this ideology simply overturned, rather repressed looking into the morass of the inevitable when it came calling.[9,10] Despite its uncomfortable Western origin, this gradually started dwelling into all developing cultures.

Death and medicine

Once 'death' became a terminology in medicine, it only asserted this position, giving a leverage to those directly associated with the dying to shy away from its poignant emotional and spiritual side that naturally came with it. The need to put off death and prolong one's remaining days became ever more urgent, even when the flicker of life was fast fading away.[11]

A change did come, when this poignancy revealed itself as a banal fear that was clinging to the very act of dying and not simply its aftermath. Kubler Ross.[12] would soon bring about the Hospice movement in England where changes in the experiences of the dying would take a more benevolent turn. Simultaneously, research using psychedelics on the terminally ill had already begun in the 1950 s and 60 s which would alter the face of medicine as it coerced into another realm.

Noyes,[13] who worked with near death experiences, emphasized on the key phases of dying, where in the final phase of transcendence, (*after initial resistance and a final appraisal of one's life*) the mystical state of consciousness occurred and personal boundaries dissipated. One felt that the sense of separation that existed in reality was fast dissolving as he was coming in harmony with everything around him. Noyes[14] explained that people who had these experiences induced in them either artificially or naturally, expressed a certain lucidity about the transition of death and rebirth. This symbolic significance of death transcendence would peek out to Western culture and lend it a perceptive glance, through psychedelic therapy a few decades prior to Noyes's observation.

Psychedelics and the historical glance

From the accounts of Grof and Halifax (1977),[11] Valentina Pavlovna Wasson, a pediatrician intrigued by the use of psychedelic mushrooms by Mexicans was the first recorded Westerner to be initiated into a sacred ritual led by a *Mazatec curandera* (*medicine woman*); this was inherent in indigenous Columbian cultures, and spread wide across Central America. The effect of the mushrooms left a deep impression upon the Wassons, and made Valentina reveal later that it could be used to study deep psychic experiences and perhaps could even be extended to other medical uses. The mushrooms were botanically identified as *Psilocybe mexicana* (Psylocybin).

Alduous Huxley, was the first to declare that psychedelic drugs could be used to assist the dying. His interest in death and its spiritual transition stemmed from his own experiences. Huxley declared that these drugs "*could make death a more conscious experience*," this was from his close encounter with the dying, when through a psychedelic-induced hypnosis, he helped his first wife in her final hours as she lay dying from cancer. On his own deathbed too in 1963, it was lysergic acid diethylamide (LSD) that relieved him.[11]

But before the West ventured out into exploring the benefits of psychedelic therapy, legend surrounding the mystical healing powers of psychedelic plants was rife across most ancient cultures. It formed an intrinsic part of all their communal rituals including death, which they understood as a form of transcending reality into the next dimension. Its symbolic meaning was to prepare one for the nascent experience and clear one's insight toward the awakening of the transient nature of consciousness.[15] This would be an extended part of a commonly shared experience, where the shaman or the wise leader would often ingest these psychedelic plants or would make the group do so through a ritualistic process.

Psilocybin, marijuana and mescaline were ritually practiced for spiritual experiences. There is evidence of the first medicinal and ritualistic use of cannabis in China in the book *Pên-ts'ao Ching*, of about 2000 B.C.;[16] its application was preponderant in an array of medical disorders, from psychological malaise to its use as an anesthetic in surgical operations.[17] Later of course the hallucinogenic opium would replace cannabis around the 8th century AD. Herodotus, the Greek historian himself witnessed the use of marijuana among the Scythians of North Central Asia around 5th century B.C. He recorded that its use was at the heart of the ceremonial core of honoring the dead.[18] The Sumerians of the Near East were among the first to use cannabis and right from Mesopotamia to Peru, marijuana use was a common ritualistic practice, the use of which also finds mention in the Old Testament.[19] The Yaqui tribe of South America religiously used psilocybin and mescaline during meditation.

A notable allusion to the psychologically penetrating influence of cannabis finds mention in the *Atharva Veda* (fourth book of the Vedas, 2000-1400 B.C.). Cannabis in India, was time honored since its association with the mythological God Siva. It was extolled for its mind altering properties and was intimately woven with the communal, religious, and medicinal context.[20] To attain deep spiritual experiences or sadhana (spiritual), this practice was unparalleled and is still common among the *Aghoras* and the *Shaivites*, of the Tantra sect. Even among the Tantric Buddhists its use is well-known. Sushruta, elucidated its therapeutic benefits for a wide range of ailments, including its use as an anesthetic for minor surgeries and as cure for fevers.[21]

Between 1893-94, the Indian Hemp Drugs Commission was authorized to look into the use of cannabis in India; they recognized its potential benefits in medicine and deemed it an important drug.[22] Despite being entrenched in the religious, cultural and medical ethos the British Indian Government in 1896 enforced an act that deterred the use of cannabis as an intoxicant. 1930 saw the Dangerous Drugs Act being passed, which even at the state level made the sale and possession of manufactured drugs, including medicinal cannabis difficult. The final nail was hammered in 1964, when the government sanctioned the Single Convention on Narcotic Drugs Act, and by mid 1980 s, the cultivation, possession and consumption of cannabis was severely penalized and came under strict vigilance of the Narcotic Drugs and Psychotropic Substances Act, 1985. Also a hallucinogen, cannabis was often referred to as "Phantastica",[23] that which causes euphoria, and is known to accentuate sensual perceptions, by distorting body boundaries and warping the sense of space and time.[23]

The active psychedelic properties of most of these hallucinogenic plants came under the scrutiny of Western scientists only recently. The psychedelic properties that were pharmacologically synthesized are: rye fungus (LSD), the psilocybin mushroom or 'magic mushrooms' (psilocybin), and the peyote cactus (mescaline).[24] Since LSD first appeared, psychiatrists and psychologists would often lend themselves the experience of the psychedelic states of temporary psychosis, which would let them trudge on the otherwise frozen territories.[25]

The word "hallucinogen" is alternately used as psychedelic, and has its roots in Greek, which literally means "to wander in the mind." Since these drugs do not actually produce true hallucinations but provokes an illusion, it is implicit that it is an effect of the drug.[26] Most of the chemical structures of these psychedelics were also found to closely resemble the chemical properties of the neurotransmitters in the human brain, so this chemical gateway would inevitably provide a sympathetic understanding of psychotic states.[27]

The psychedelic trip

Since its early days LSD began to be seen as a convenient way "*of gaining access to the chronically withdrawn patient*" and would soon gain repute as an adjunct to psychotherapy.[28] Others would soon follow, and it was Sandison in 1953 who opened the first LSD clinic in England. Sandison and his group were to opine that LSD therapy worked best with the obsessionally neurotic and other anxiety groups.[29] But, it was Osmond who would revolutionize its use with chronic alcoholics in 1957.[30] He would use high doses of LSD (300 mcg. or more), sometimes in combination with the other hallucinogens, and soon the wave "psychedelic therapy" caught on after Osmond first coined it. Later, psychedelic psychotherapy, as an adjunct would invigorate the barriers of consciousness to unravel its mystical qualities across a range of therapeutic settings.[31,32] Before Kast and Collins in 1964.[33] embarked on their research on the use of psychedelics with the dying, reports from the

Sherwood *et al.*, and the Savage *et al.*, studies had already shed light on how most patients overcame their fear of death.

Kast's early work in the 1960 s on analgesics led him to LSD, which he learnt could "*markedly distort body image and alter body boundaries*", besides LSD could obstruct the body's own need to selectively concentrate on the physiological sensation of pain. In 1964, he and his colleague, Collins published their work on LSD where they compared its pain relieving effects with the opiate analgesics, Dilaudid (dihydromorphinone) and Demerol (meperidine) on a group of patients with severe physical pain, among whom were several with different types and stages of cancer. LSD turned out to be a superior drug. What struck them was that patients after their LSD experience could easily cast off their fear of an impending death. What followed later was his study on 128 patients with metastatic cancer, in a nonpsychotherapeutic setting, but where he extended it to their psychological aspects of attitudes, emotions and sleep patterns associated with their illness and death. An administered dose of 100 µg of LSD not only remarkably reduced their pain, that lasted for about 12 hours, but also reduced its intensity for 3 weeks. Ten days following the session, sleep too improved in the group and they seemed less occupied with death.[11,25]

1966 saw Kast being intensely occupied with the personal and philosophical experiences of patients with terminally malignant diseases who had but just a few weeks or months ahead of them, an imminent reality they were aware of. Like before, not only did 100 µg of LSD have a relieving effect on physiological pain, emotions and sleep pattern but Kast went on to describe, "*happy, oceanic feelings*", "that would overpower the fear of death and would bring in a sense of community with which they would perceive themselves and those around them with a certain philosophical and religious precept that was beyond the rationalization of any numerical data or graphs".[11,34]

Kast had set the mould from which future research would take shape. Gary Fisher,[35] another researcher in 1970 in his work highlighted the more personal experiences of the dying, and he discussed this in light of transcendental experience gained from practice, either spiritually or induced artificially through psychedelics. Fisher emphasized on the experiences of the dying patient whose concern about death had mitigated as he began to see it less as a physical departure and more as a continuity of life force.

Around the 1960 s simultaneous work on LSD exploring its psychotherapeutic benefits was being headed by Stainslav Grof in Prague, Czechoslovakia.[11] Grof's work with LSD was based on the theory and practice of psychoanalysis on psychiatric patients which would soon grow out of it to become an independent school of its own and take into its ambit the transpersonal and transcendental experience. This would over the years be integrated into the psychedelic therapy associated with the dying. Influenced by his work with psychiatric patients who reported a mitigated feeling toward their own fear of death with LSD therapy, Grof went on to inculcate these same ideas with those patients for whom death was an imminent reality, and this led him to his work with cancer patients. He would soon work with other researchers at Spring Grove, which later became the Maryland Psychiatric Research Center (MPRC) using a specific form of psychedelic therapy with the terminally ill.[36]

What began in MPRC in 1963, as an exploration of the therapeutic potential of LSD on alcoholics and neurotics would soon find its way, although unexpectedly attending to the terminally ill. This would unfold in an event when one of its own research team member developed metastic cancer, and in the face of it underwent severe depression and anxiety; LSD therapy proved to be a peak personal experience for her wherein she could confront and resolve her fears of the unknown.[11]

What was initiated as psychedelic therapy was soon dubbed as psychedelic peak therapy,[36] as one often attained a peak transcendental experience with a high dose of psychedelics (350-400 mcg.), but for this to be conducive, patients would initially undergo intensive psychotherapy that would last at least 20 hours.

The work at Spring Grove would grow to become the most well-documented psychedelic research of that time;[37] and research would remain unrelenting until 1976, when the Comprehensive Drug Abuse Prevention and Control Act of 1970 was enforced under political pressure because of the escalating problems of drug abuse.[37]

Dipropyltryptamine (DPT), another psychedelic was also examined in two cancer studies in lieu of the LSD, since its properties were similar to LSD but was less time consuming.[38] It took about 1 ½ to 6 hours to act, and its effects too wore off easily unlike the LSD that demanded a considerable amount of time. Post-therapeutically DPT's benefits would mimic LSD. It was suggested to be a better alternative than LSD, but because of its quick onset, patients often found the sudden psychological upheaval overwhelming.[39]

Psychedelic research would soon see its decline in the U.S., and whatever sporadic research continued would be published anecdotally. Even though it was interred deep in medical research in the 1950 s and 1960 s,[40] drug use in the recreational scene attained a cult status in the 1960 s, following which it became a medical and sociopolitical taboo.[41]

Another class known as the entactogens comprising of the agent MDMA (3,4-methylenedioxymethamphetamine), has been popular as the street drug ecstasy since the last two decades. In the early 80 s, it begun to be used in the psychotherapeutic setting, as it enhanced one's state of contemplative insight,[42] and helped delve into the repressed parts of the psyche. This it did by mitigating fear in an otherwise emotionally surcharged moment;[43] which is why its potent use was grasped for the terminally ill.[44]

The classical psychedelics (LSD and psilocybin) are nonaddictive, known not to cause any physiological dependency and are nontoxic[45-47] which is why current researchers are making a stab at bringing back these drugs for their exceptional use in relieving the existential encumbrance that comes with the terminally ill.

Psychedelic research is once again starting up, but cautiously. Research continued in Europe throughout the 80 s, but was mostly restricted to private practice. It was in Switzerland, however, where it met the least resistance, and research continued despite the world-wide ban in 1971. Licenses were granted by the government for exclusive research in MDMA, psilocybin, and LSD psychotherapy in 1988.[25,48]

Current wave

Contemporaneous research into psychedelics is delicately being burrowed out of its political tentacles that has not just rendered it deleterious to contemporary health but also kept tightening its fist around any attempted research that could have otherwise proved its authenticity. What also discouraged its use was that pharmaceutical companies would not stand to gain by it as there were no patents to be had and also these drugs do not require regular use. A few sessions of therapy were mostly enough, and sometimes even a single LSD trip could alter one's life.

Most of the current research is being targeted on patients who have developed secondary anxiety-related disorder associated with end-stage cancer, and were refractory to anxiolytic therapy and psychotherapy.[45] Their line of work is inspired by the earlier works of Kast, in which the drug therapy is used as an adjunct with psychotherapy.

LSD and psilocybin are both structurally similar to the neurotransmitter serotonin and can directly affect its pathways in the brain. A study using psilocybin, is being conducted in the University of California in Los Angeles UCLA, USA, by Charles Grob, who waited more than 10 years before he got the approval for a pilot study in 12 patients with advanced-stage cancer, who had developed severe anxiety disorder. The reason why psilocybin was opted instead of LSD is because its action is shorter, and also the effects can be easily controlled.[45,49] Patients were placebo-controlled and assisted with psilocybin in the double-blind study. Implicit to the study is that the psilocybin group will fare better than the controls while they experience reduced pain, anxiety and depression, the effects of which, it is presumed will continue beyond the study period; and will also curb their need for anxiolytic and analgesic therapy. Influenced by Grob's work a similar study was undertaken by Sameet Kumar, TBD, USA in stage IV melanoma patients.[49]

Similar research has been initiated by John Halpern at the McLean Hospital, Harvard Medical School, using MDMA as adjunct to psychotherapy for patients with anxiety secondary to end-stage cancer. In May 2012, the annual report on the Swiss study by Peter Gasser was submitted by the Multidisciplinary Association for Psychedelic Studies (MAPS). Gasser and his team are conducting research on LSD-assisted psychotherapy in twelve subjects with anxiety related to advanced-stage illness (cancer, metabolic and autoimmune diseases).

Psilocybin-assisted psychotherapy is also underway at the Johns Hopkins University, Baltimore, USA; where the principal investigator is Roland Griffiths. This study will accommodate patients with early, nonterminal cancer.

The way out

Ethical concerns for the most part will linger with the use of these psychedelic drugs in human subjects, but to grasp the full extent of these ethical concerns behind such research one also needs to empathize with the views of patients changing perspective toward their lives, particularly when they see the inevitability of a perishable self. But a psychedelic trip enhanced realization of continuity, which dissipates the ego into a boundary-less whole is what seems comforting to the dying.[50] Soon after LSD caught on a new wave in medical research, Albert Hoffman, who engineered its invention opined that psychedelics could see its way into the future through transpersonal psychology.[51] He went on to add that "*it was only through this route of transpersonal psychology that we could gain access to the spiritual world*."[51]

Stanislav Grof was a proponent of this school of transpersonal therapy, along with Abraham Maslow, who posited that altered states of consciousness (ASCs) were the key to realizing one's psychological well being. Psychedelic-induced ASCs "could catalyze a therapeutic response" by adding meaning to therapy.[50] This practice was well known among most spiritual disciplines, particularly Buddhism where most of the monks had had experiences with psychedelics, in keeping with their traditional vow.

When we go back to the history of psychedelic research it is not hard for anyone to see that field held much promise in its incipient stages, before it was cracked down in the 1960 s and 70 s. First the complacency in which researchers and therapists controlled their supply of LSD and later the booming of the counter-culture movement led by the Harvard psychologist Tim Leary led to its indiscriminate use in the most profane way. So the grip tightened more out of societal concerns than any medically linked problems with LSD and the other psychedelics.[52]

A favorable shift in the trend toward bringing psychedelics back into the research was because of researchers like Strassman and the concerted efforts by organisations like the Multidisciplinary Association for Psychedelic Studies (MAPS) and the Heffter Organization, which have pioneered the medical research of these drugs.

For research to continue, and remain unscathed from political breaches, it becomes the responsibility of the individual or researchers directly associated with it to make a conscious effort to steer clear from the lackadaisical attitude of the past that had created much of the unnecessary moral and medical hysteria about psychedelic use.[53] Some of the scandals involved the early known psychotomimetic research sponsored by the CIA under (MK-ULTRA),[54] where LSD was being explored as the truth serum had done enough to tarnish its repute; but, even after a prohibition in conventional research, psychedelic use proliferated as an underground culture, and legal restrictions had little to do with it. So the problem is not whether medical research would give recreational use more leverage and escalate its abuse, the question is how much of this medical ease will actually unrestrain itself from its own excesses. One could see that the removal of criminal penalization for use of non-addictive drugs did little to escalate its recreational use in Holland and Portugal.

Lastly, we are bound by this inescapable concern of anxiety being inherent to our condition; it is the core of who we are, something that we cannot put an end to, because such an end would require the annihilation of the ego-self first (existential school). But because it cannot be overcome therapeutically,[55,56] since one cannot face the terrible possibility of one's condition (our mortality) without anxiety; we had to repress this truth. We have fractionized reality to an extent where we can partially deal with this anxiety, by confining our world within its narrow realm, where we have accessibility and control. But when one is faced with the imminence of death, this anxiety cracks open in all its floridness, the paradoxical stance of the death wound undoing the birth wound conditions itself once again. Death transcending into another alternate realm is the central theme of most religious traditions, but the problem ascends when we try to demythologize these myths,[1] when we try and wheedle out their deeper meaning. The problem is we cannot extricate it out from the myth of our own mechanized language that we are used to (language of modern science), since we can only project ourselves from what we have learnt to learn, with our own cognitive apparatus that does not safeguard us from this duality of life and death.

So psychedelic therapy is not a cure to this eternal morass, it eases our burden alright, giving us a peek into what might be, but we never know, but as long as it helps one wade through one's existential fear, or just numb the reality of pain, then why not? Anxiety dissipates here, the unknown becomes more acquainted, and the knowing becomes obsolete and we feel cured like "the artist who carries death in him like a good monk his breviary" (Boll).

Summary

Background

Psilocybin is a serotonin receptor agonist that occurs naturally in some mushroom species. Recent studies have assessed the therapeutic potential of psilocybin for various conditions, including end-of-life anxiety, obsessive-compulsive disorder, and smoking and alcohol dependence, with promising preliminary results. Here, we aimed to investigate the feasibility, safety, and efficacy of psilocybin in patients with unipolar treatment-resistant depression.

Methods

In this open-label feasibility trial, 12 patients (six men, six women) with moderate-to-severe, unipolar, treatment-resistant major depression received two oral doses of psilocybin (10 mg and 25 mg, 7 days apart) in a supportive setting. There was no control group. Psychological support was provided before, during, and after each session. The primary outcome measure for feasibility was patient-reported intensity of psilocybin's effects. Patients were monitored for adverse reactions during the dosing sessions and subsequent clinic and remote follow-up. Depressive symptoms were assessed with standard assessments from 1 week to 3 months after treatment, with the 16-item Quick Inventory of Depressive Symptoms (QIDS) serving as the primary efficacy outcome. This trial is registered with ISRCTN, number ISRCTN14426797.

Findings

Psilocybin's acute psychedelic effects typically became detectable 30-60 min after dosing, peaked 2-3 h after dosing, and subsided to negligible levels at least 6 h after dosing. Mean self-rated intensity (on a 0-1 scale) was 0.51 (SD 0.36) for the low-dose session and 0.75 (SD 0.27) for the high-dose session. Psilocybin was well tolerated by all of the patients, and no serious or unexpected adverse events occurred. The adverse reactions we noted were transient anxiety during drug onset (all patients), transient confusion or thought disorder (nine patients), mild and transient nausea (four patients), and transient headache (four patients). Relative to baseline, depressive symptoms were markedly reduced 1 week (mean QIDS difference -11.8, 95% CI -9.15 to -14.35, *p*=0.002, Hedges' g=3.1) and 3 months (-9.2, 95% CI -5.69 to -12.71, *p*=0.003, Hedges' g=2) after high-dose treatment. Marked and sustained improvements in anxiety and anhedonia were also noted.

Interpretation

This study provides preliminary support for the safety and efficacy of psilocybin for treatment-resistant depression and motivates further trials, with more rigorous designs, to better examine the therapeutic potential of this approach.

Funding

Medical Research Council.

Research in context

Evidence before this study

We searched PubMed up to Jan 30, 2016, using the terms "psilocybin", "hallucinogens", "psychedelics", and "depression". We did not find any clinical trials assessing psilocybin as a treatment for depression, but we did find population analyses, review articles, and imaging studies lending support to this approach. We also found one report documenting enduring decreases in depressive symptoms after a single dose of psilocybin in a randomised controlled trial of psilocybin-assisted psychotherapy for end-of-life anxiety, one report on an open-label trial showing rapid decreases in depressive symptoms that endured for up to 21 days after a single dose of ayahuasca, and two early reports or case studies on the effects of lysergic acid diethylamide on "neurotic" and depressive symptoms describing "improvements", albeit without validated measures of symptom severity.

Added value of this research

To our knowledge, this is the first investigation of the safety and efficacy of psilocybin as a treatment for major depression. Our findings imply that psilocybin might have value as a treatment option in the management of treatment-resistant depression. Single oral administrations of 10 mg (safety dose) and 25 mg (treatment dose) psilocybin were well tolerated and led to enduring reductions in symptom severity after the two sessions.

Implications of all the available evidence

The results of this small-scale feasibility study should help to motivate further research into the efficacy of psilocybin with psychological support for major depression. Larger-scale randomised controlled trials are warranted to better examine the potential of psilocybin as a treatment option for this highly prevalent, disabling, costly, and difficult-to-treat disorder. More broadly, the present study should help to catalyse the re-emergence of a promising research area in psychiatry.

Introduction

Psilocybin is a naturally occurring plant alkaloid found in the *Psilocybe* genus of mushrooms. *Psilocybe* mushrooms have been used for millennia for healing purposes, but were only discovered by modern science in the late 1950s.[1,2] Psilocybin is a prodrug of psilocin (4-hydroxy-dimethyltryptamine), a serotonin receptor agonist and classic psychedelic drug whose principal psychoactive effects are mediated by serotonin 2A (5-HT_{2A}) receptor agonism.[3] Psilocybin therefore has a novel pharmacology in the context of currently available antidepressant medications, because selective serotonin-reuptake inhibitors are not direct 5-HT_{2A} receptor agonists.

Enhanced cognitive flexibility,[4] associative learning,[5] cortical neural plasticity,[6] and antidepressant responses have been reported with 5-HT_{2A} receptor agonism in animals,[7] and increased and sustained improvements in wellbeing[8] and optimism[9] have been observed after psychedelic experiences in human beings. Findings from human imaging studies with psilocybin have supplemented these discoveries, showing changes in brain activity suggestive of antidepressant potential; for example, a range of effective antidepressant treatments have been found to normalise hyperactivity in the medial prefrontal cortex and we found reduced blood flow in this region with intravenous psilocybin.[10] Moreover, data obtained from large-scale population studies have recently challenged the view that psychedelics negatively affect mental health,[11-13] with one study's findings showing lower rates of psychological distress and suicidality among people who had used psychedelics within their lifetime than among those who used no psychedelics but an equivalent amount of other drugs.[11] In modern trials, psychedelics have been found to reduce anxious,[14,15] depressive,[15,16] and obsessive-compulsive symptoms,[17] as well as addictive behaviours,[18,19] often for several months after just one or two exposures. Extensive historical and modern evidence now supports the view that, administered in a controlled environment with appropriate support, psychedelics have a favourable safety profile.[20]

Depression is a major public health problem; it is a leading contributor to the global burden of disease, affecting hundreds of millions of people worldwide, and costing the USA alone more than US$200 billion each year.[21] Antidepressant medications and cognitive behavioural therapy can be effective for some patients, but around 20% do not respond to any intervention, and many of those who do respond, eventually relapse.[22] We aimed to investigate the safety and feasibility of psilocybin in patients with treatment-resistant depression, and to establish an initial impression of its efficacy. We postulated that the treatment would be well tolerated and depressive symptoms would be substantially reduced from baseline at all assessment points, for up to 3 months after treatment.

Methods

Study design and participants

This was an open-label feasibility study in patients with treatment-resistant depression; there was no control group. Patients, investigators, raters, and statisticians were not masked to treatment assignment, and all participants received the study intervention (psilocybin administered in two dosing sessions; an initial safety [low] dose and a subsequent treatment [high] dose). The inclusion criteria were major depression of a moderate to severe degree (17+ on the 21-item Hamilton Depression Rating scale [HAM-D]), and no improvement despite two adequate courses of antidepressant treatment of different pharmacological classes lasting at least 6 weeks within the current depressive episode.[23] Exclusion criteria were: current or previously diagnosed psychotic disorder; immediate family member with a diagnosed psychotic disorder; medically significant condition rendering unsuitability for the study; history of serious suicide attempts (requiring hospitalisation); history of mania; blood or needle phobia; positive pregnancy test at screening or during the study; and current drug or alcohol dependence.

Information about the study's recruitment was sent to general practitioners via the North West London Clinical Research Network. However, patients were also allowed to self-refer to the study if they were UK residents. In every case, patients initiated contact with the research team (via email, letter, or telephone), were sent a study information sheet, and a subsequent telephone screening was arranged, during which the lead psychiatrist on the trial (MBo) obtained information about the patient's demographics, medical and psychiatric history, and other key inclusion or exclusion criteria. The patient's general practitioner or psychiatrist provided written documentation of the patient's diagnosis and mental health background in every case.

This trial received a favourable opinion from the National Research Ethics Service London - West London, was sponsored and approved by Imperial College London's Joint Research and Compliance Office (JRCO), and was adopted by the National Institute for Health Research Clinical Research Network. The National Institute for Health Research/Wellcome Trust Imperial Clinical Research Facility gave site-specific approval for the study. The study was reviewed and approved by the Medicines and Healthcare products Regulatory Agency (MHRA). All participants provided written informed consent. Study and data monitoring was carried out independently by the Imperial Clinical Research Facility and JRCO.

Procedures

Psilocybin was obtained from THC-pharm (Frankfurt, Germany) and formulated into the investigational medicinal product (5 mg psilocybin in size 0 capsules) by Guy's and St Thomas' Hospitals' Pharmacy Manufacturing Unit (London, UK). A Home Office Licence for storage and dispensing of Schedule One drugs was obtained.

Screening consisted of written informed consent, a thorough evaluation of the patient's physical and mental health background, a psychiatric interview (Mini-International Neuropsychiatric Interview), clinician assessments of depression severity (the 21-item HAM-D and the Montgomery-Åsberg Depression Rating Scale [MADRS], and Global Assessment of Functioning [GAF]; all assessed by MBo), and additional patient-rated scales (16-item Quick Inventory of Depressive Symptoms [QIDS], Beck Depression Inventory [BDI - original version], Spielberger's State-Trait Anxiety Inventory [form 2, trait version only; STAI-T], and the Snaith-

Hamilton Pleasure Scale [SHAPS]). Patients also received a thorough physical health check, consisting of an electrocardiogram, routine blood tests, blood pressure, heart rate, and physical examination. At the end of screening, eligible patients were given an opportunity to meet with the two clinical psychiatrists who would support them through the remainder of the trial.

Eligible patients attended a subsequent visit involving a baseline functional MRI (fMRI) scanning session lasting 60 min, followed by an extensive preparatory session with their allocated psychiatrists; fMRI data will be reported elsewhere. This preparatory session involved inviting the patient to talk openly about their personal history (including thoughts on the origins of their depression), a discussion of psilocybin's psychological effects, and simulation of aspects of the dosing session itself, such as listening to a sample of the session music while wearing eyeshades. The preparatory session typically lasted for 4 h, with lunch and breaks provided.

Patients enrolled in the study attended two subsequent dosing sessions that were separated by 7 days. No more than one patient was dosed on any given day. Patients arrived at the research facility (Imperial Clinical Research Facility) at 0900 h, gave a urine sample for drugs of abuse (including amphetamines, benzodiazapines, opiates, and cannabinoids), performed a breathalyser test for alcohol use, and completed interim QIDS, BDI, and STAI-T assessments to ensure no substantial deviation from baseline measures. They were then taken to a dosing room that was pre-decorated (eg., with low lighting). Patients were invited to relax on a ward bed in a supine or reclined position and music was played through high-quality stereo speakers and earphones. The two psychiatrists sat on either side of the bed. Patients were supervised at all times by at least two staff members.

Dosing commenced at 1030 h in every case. Patients received a low oral dose of psilocybin 10 mg (two 5 mg capsules) on a first dosing day and a high oral dose of psilocybin 25 mg (five 5 mg capsules) on a second dosing day, separated by 1 week. Blood pressure, heart rate, and observer ratings of the intensity of psilocybin's acute psychoactive effects (0-4, with 0 signifying no effects and 4 signifying extreme effects[8]) were measured at baseline (typically 5 min before dosing) and 30, 60, 120, 180, 240, 300, and 360 min after dosing. Subjective ratings of the acute altered state of consciousness using the revised 11 dimension altered states of consciousness questionnaire (11D ASC)[24] were completed 6-7 h after dosing.

Psychiatrists adopted a non-directive, supportive approach, allowing the patient to experience a mostly uninterrupted inner "journey". Check-ins (ie., asking the patient how they are feeling) occurred at the same timepoints as the physiological recordings. Tranquilising medications (oral lorazepam and risperidone) were available if necessary. The phenomenology of the acute experience, including accounts of the nature of the therapeutic support provided before, during, and after the experience, and considerations related to the music selection and other aspects of the clinical setting, will be discussed in separate publications.

Return transport from the research facility was organised ahead of dosing sessions. Patients were taken to and from the sessions accompanied by a close friend or relative, and had the option of staying overnight in accommodation adjacent to the hospital. Emergency contact details were provided, and patients confirmed their safe return from the research facility.

Patients were contacted via telephone 1 day after their low-dose session to check on their well-being and monitor for any adverse events. Patients returned to the research facility 1 day after their high-dose session for a post-treatment fMRI scan lasting 60 min. After the fMRI scan, patients completed interim questionnaires (QIDS, STAI-T, and HAM-D), and were invited back to the research facility where they were met by their psychiatrists to discuss their experience the previous day.

Patients attended one further study visit to the research facility 1 week after their high-dose session, during which all baseline questionnaires and assessments were repeated and an opportunity was provided for further psychological debriefing (the 1 week follow-up visit). Assessments of HAM-D, MADRS, and GAF were again done by MBo. Subsequent assessments of clinical progress were done via email 2, 3, and 5 weeks after the high-dose session; we assessed only QIDS during subsequent follow-up, so as not to overload the patient. Final follow-up was done remotely at 3 months after the high-dose session, and included QIDS, BDI, STAI-T, and SHAPS. Patients were made aware that they could contact the study psychiatrists at any time if their depression deteriorated. Figure 1 summarises the screening, intervention, and follow-up procedures in this study.

Outcomes

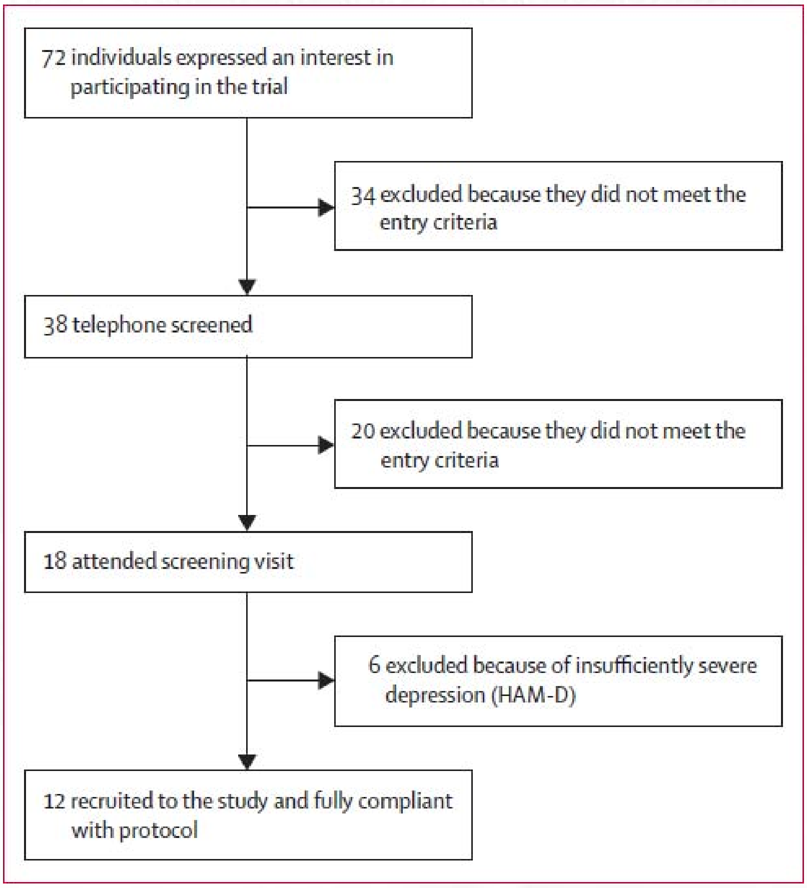
The main objective of this study is to optimise the protocol for the administration of oral psilocybin in this patient group, while gaining an initial impression of treatment efficacy. The primary outcome measure to assess feasibility was patient-rated subjective intensity of psilocybin's effects, which we report on a 0-1 scale. We assessed the safety of the intervention through clinical monitoring during and after dosing sessions, and during 3 months of face-to-face and remote follow-up. We also aimed to assess the preliminary efficacy of psilocybin in patients with treatment-resistant depression; the primary outcome measure for this endpoint was mean change in the severity of self-reported depressive symptoms (with the 16 item QIDS) from baseline to 1 week after the high-dose psilocybin session. The QIDS was chosen as the primary outcome measure due to its brevity, increasingly widespread use, and validity at 1 week intervals.[25] We chose to assess the primary efficacy endpoint at 1 week after the high-dose session to allow comparison with previous studies of ketamine infusion for treatment-resistant depression;[26] the low-dose session was conceived a priori as a safety session rather than a treatment session. We also assessed change in BDI, STAI-T, and SHAPS between baseline and 1 week and 3 months of follow-up, and change in HAM-D, MADRS, and GAF between baseline and 1 week of follow-up.

Statistical analysis

In this feasibility study, we did not perform a formal power calculation. We planned to recruit 12 patients to provide an initial impression of the tolerability and efficacy of this novel treatment approach. A subsequent protocol amendment (Oct 6, 2015) increased the recruitment to 20 patients to provide statistical power for fMRI imaging. Here, we report findings for the 12 patients initially enrolled; outcome and fMRI data for all 20 patients will be reported separately.

Due to the small population, two-tailed Wilcoxon signed ranks tests were performed for non-parametric data. Two-tailed *t* tests were also performed and the relevant *t* values are provided in the appendix. We provide 95% CIs around the mean differences. We calculated effect sizes using the Hedges' g formula, which is more appropriate for small sample sizes. Hedges' g values are very similar to Cohen's d values for dependent data.

This trial is registered with the ISRCTN registry, number ISRCTN14426797. The registration was initiated on March 30, 2015, and finalised on July 7, 2015 (delay caused by administrative issues); recruitment started on April 21, 2015, after initiation of public registration.



72 individuals expressed an interest in participating in the trial
34 excluded because they did not meet the entry criteria
38 telephone screened
20 excluded because they did not meet the entry criteria
18 attended screening visit
6 excluded because of insufficiently severe depression (HAM-D)
12 recruited to the study and fully compliant with protocol

Figure 2 - Trial profile.

Role of the funding source

The study funder had no role in the design, data collection, analysis, interpretation, or writing of the report. The corresponding author had full access to all of the data in the study and had final responsibility for the decision to submit for publication.

Results

Enrolment started on May 1, 2015, and finished on Aug 25, 2015. 72 people were initially considered for the study, most of whom self-referred after hearing about this trial through public outreach work (eg., public presentations by the investigators and media reports). 38 were considered appropriate for a telephone screen, from which 18 were invited for a formal screening visit, and 12 were ultimately recruited for the trial (figure 2), of whom ten were self-referrals. Patients' demographic and clinical characteristics are shown in table 1. Nine of the 12 patients met criteria for severe or very severe depression at baseline (BDI score ≥30), with the remaining three patients meeting criteria for moderate depression (BDI score 19 to <30). 11 patients had received some form of psychotherapy before participation in the study.

Table 1: Baseline and demographic characteristics, by patient.

The acute effects of psilocybin were well tolerated by all of the patients and no serious or unexpected adverse events occurred. Mean self-rated intensity of psilocybin experience was 0.51 (SD 0.36) for the low-dose session and 0.75 (0.27) for the high-dose session (difference 0.24 [95% CI 0.06-0.41], Z -2.4, *p*=0.019). No patients required tranquilising medications (oral lorazepam and risperidone) during the dosing sessions. Psilocybin's acute psychedelic effects typically became detectable between 30 min and 60 min after dosing, peaked between 2 h and 3 h after dosing, and subsided to negligible levels at which the patient could be assessed for discharge at least 6 h after dosing (appendix). Self-rated experiences on the 11D-ASC questionnaire from the two sessions are shown in the appendix. Results from interim patient questionnaires (QIDS, BDI, and STAI-T), done immediately before the low-dose session to monitor for substantial changes since enrolment, did not differ from baseline (data not shown). Interim questionnaires done the day after the high-dose session showed some reduction in depressive symptoms (data for HAM-D in appendix; data for QIDS and STAI-T not shown).

	Severity	Timing or onset	Duration
Patient 1			
Transient anxiety	Mild	Onset of both sessions	60 min

Transient headache	Mild	Day after high-dose session	One day only
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-120 min
Patient 2			
Transient anxiety	Mild	Anticipatory anxiety only (both sessions)	30 min
Patient 3			
Transient anxiety	Mild	Anticipatory anxiety only (both sessions)	30 min
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min
Patient 4			
Transient anxiety	Mild (low dose), moderate (high dose)	Onset of both sessions and peak of high dose	60 min (low dose), 120 min (high dose)
Transient nausea	Moderate	Onset phase of high-dose session	Arose and subsided within 60 min
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min
Transient paranoia	Mild	Peak of high-dose session	Arose and subsided within 30 min
Patient 5			
Transient anxiety	Moderate (low dose), severe (high dose)	Onset of both sessions and peak of high dose	60 min (low dose), 150 min (high dose)
Transient headache	Mild	Day after high-dose session	One day only
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-120 min
Patient 6			
Transient anxiety	Mild	Anticipatory anxiety only (both sessions)	30 min
Patient 7			
Transient anxiety	Mild	Anticipatory anxiety only (both sessions)	30 min
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min
Patient 8			
Transient anxiety	Mild or negligible	Anticipatory anxiety only (both sessions)	30 min
Patient 9			
Transient anxiety	Mild (low dose), moderate (high dose)	Onset of low-dose and high-dose session	60 min (low dose), 150 min (high dose)
Transient headache	Mild	Day after high-dose session	One day only
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min
Patient 10			
Transient anxiety	Mild	Onset of both sessions	60 min
Transient nausea	Mild	Onset and peak of low-dose session	Subsided after 90 min
Transient headache	Mild or moderate	Day after high-dose session	2 days
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min
Patient 11			
Transient anxiety	Moderate (both sessions)	Onset phase and peak of both sessions	150 min (both sessions)
Transient nausea	Mild (high dose)	Onset phase of high-dose session	Arose and subsided within 60 min
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min
Transient paranoia	Mild	Peak of low-dose session	Arose and subsided within 60 min
Patient 12			
Transient anxiety	Mild	Anticipatory anxiety only (both sessions)	30 min
Transient confusion	Mild (core drug effect)	Peak of both sessions	60-180 min

Table 2: Adverse events by patient.

The most common adverse events were transient anxiety (mostly mild) during drug onset (n=12), transient confusion or thought disorder (n=9), mild and transient nausea (n=4), and transient headache (n=4; table 2). These adverse events were expected psychological effects of psilocybin. Subacute headache typically presented 1 day after the psilocybin session, and subsided after 1-2 days. Paranoia presented in only one patient, but this was mild and transient. No prolonged psychotic symptoms were observed in any of the patients. One patient contacted the study psychiatrists during the 3 months of follow-up due to deterioration of their depression, and was referred to their general practitioner.

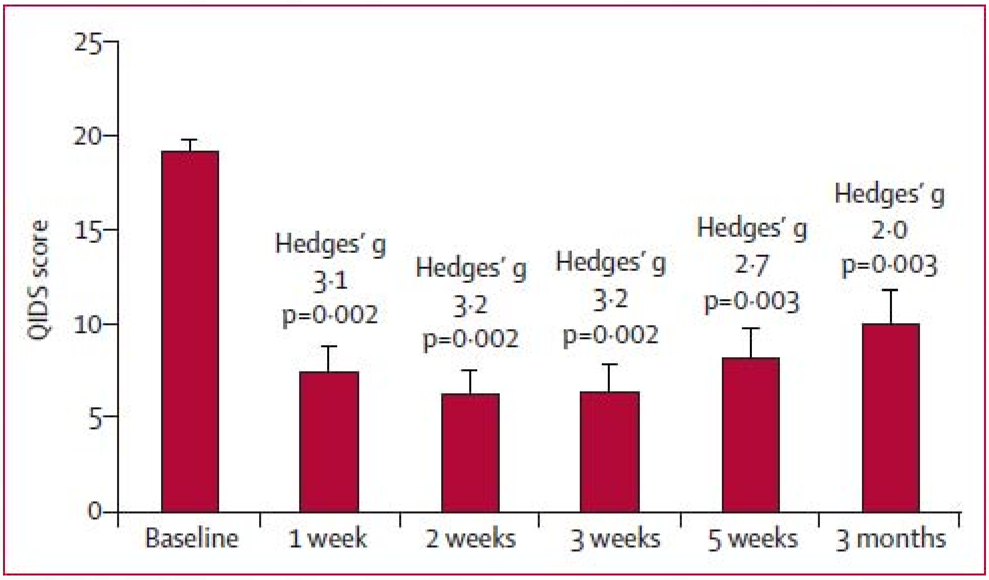

Figure 3 - Mean depression severity (QIDS) over time.
Depression severity determined by self-rated 16-item QIDS. QIDS scores of 16-20 are considered to reflect severe depression, scores of 11-15 are considered moderate depression, scores of 6-10 are considered mild depression, and scores of 5 and less are considered absent depression. All post-treatment assessments were obtained after the high-dose session (ie., 1 week post-treatment refers to 1 week after the high-dose session). Hedges' g values versus baseline are shown. QIDS=Quick Inventory of Depressive Symptoms.

QIDS depression scores were significantly reduced from baseline to 1 week and 3 months post-treatment, with the maximum effect at 2 weeks (figure 3, table 3). BDI and clinician-administered ratings confirmed these results (figure 4, table 3). All patients showed some reduction in depression severity at 1 week that was sustained in the majority for 3 months (appendix). According to standard criteria for determining remission (eg., a score of ≤9 on the BDI), eight (67%) of the 12 patients achieved complete remission at 1 week and seven patients (58%) continued to meet criteria for response (50% reduction in BDI score relative to baseline) at 3 months, with five of these (42%) still in complete remission (figure 4, table 3). STAI-T anxiety scores were also significantly reduced at 1 week and 3 months post-treatment, as were SHAPS anhedonia scores for 1 week and 3 months post-treatment (table 3).

Follow-up refers to the period starting after the second (high-dose) administration of psilocybin. Clinician-administered ratings (HAM-D, MADRS, and GAF) were completed only at baseline and 1 week after the high-dose session. QIDS=Quick Inventory of Depressive Symptoms. BDI=Beck Depression Inventory. STAI-T=State-Trait Anxiety Inventory. SHAPS=Snaith-Hamilton Pleasure Scale. HAM-D=Hamilton Depression Rating scale. MADRS=Montgomery-Åsberg Depression Rating Scale. GAF=Global Assessment of Functioning. *Compared with baseline.

Table 3: Clinical ratings at baseline and follow-up.

Discussion

In this open-label, single-arm pilot study, we sought to examine the feasibility of administering psilocybin to patients with treatment-resistant depression as a prelude to a larger randomised controlled trial. Our results support the view that, done with appropriate safeguards (eg., careful screening and adequate therapeutic support), psilocybin can be safely administered to this patient group.

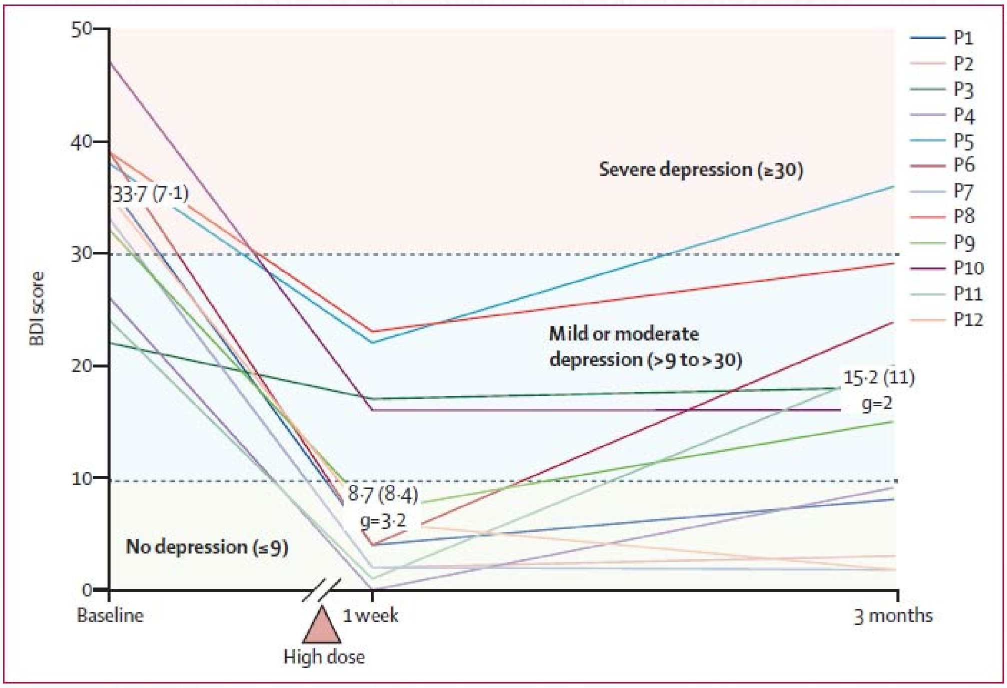

Figure 4 - Depression severity (BDI) over time, by patient.
Figure shows depression severity (BDI) over time plotted for each of the 12 patients. Mean values (SD) are shown as well as the relevant effect sizes (Hedges' g) versus baseline. BDI=Beck Depression Inventory.

Because this was a small-scale feasibility study with an open-label design, strong inferences cannot be made about the treatment's therapeutic efficacy. However, the data do suggest that further research is warranted. The response rate to psilocybin was 67% (n=8) at 1 week after treatment (HAM-D and BDI), and seven of these eight patients also met criteria for remission. Moreover, 58% (n=7) of the patients maintained their response for 3 months, and 42% (n=5) remained in remission. It is also worth noting that psilocybin has a favourable toxicity profile and is not associated with compulsive drug-seeking behaviours in animals or human beings. The side-effects that we noted were minor, and expected in light of previous studies of psilocybin.[27]

Spontaneous recovery in refractory depression is rare, and many of the patients in the present study reported having depression for much of their adult lives (mean estimated illness duration 17.8 years [SD 8]). Key questions for future research therefore should address why the therapeutic effect observed in the present study is so large, and if it can be replicated when tighter experimental controls are introduced. Because the treatment in our study consisted of not just two psilocybin administrations but also psychological support before, during, and after these sessions, as well as a positive therapeutic environment for the sessions, the relative effects of these factors need to be determined, which can only be done by conducting further trials with appropriate control conditions.

A logical next step would be to carry out a placebo-controlled randomised trial in which the level of therapist contact is consistent between conditions. This would enable any between-group differences in clinical outcomes to be attributed to psilocybin rather than the psychological support provided. However, a positive interaction between these variables seems likely, and inert placebo-based blinds are known to be ineffective in studies involving conspicuous experimental interventions, because patients can easily discern whether they are in the active condition or not. Use of an active placebo for the control condition might therefore be worth considering. Additionally, randomised comparative efficacy trials (eg., with an optional crossover component) incorporating another treatment for refractory depression (eg., ketamine infusion) could also be explored.

The magnitude and persistence of the antidepressant effects observed here are not incongruent with what has been observed previously with psilocybin in chronic psychiatric conditions. For example, 80% of long-term heavy tobacco smokers demonstrated abstinence from smoking 6 months after two treatment sessions with psilocybin.[18] Alcohol-dependent patients demonstrated significantly reduced drinking behaviours over 8 months after one or two psilocybin sessions.[19] Significantly decreased anxiety and depression scores were observed 3 and 6 months after a single dose of psilocybin in patients with anxiety related to end-stage cancer,[15] and improvements in well-being lasting for more than 1 year were observed in healthy individuals given a single dose of psilocybin.[8] Rapid and enduring decreases in depressive symptoms were also recently found in a small-scale feasibility trial involving the psychedelic brew, ayahuasca.[16]

It is important to consider the limitations of this pilot study; for example, although all patients showed some clinical improvements for at least 3 weeks after treatment, and no serious or unexpected adverse reactions were observed, enduring improvements beyond 3 weeks were not observed universally, and five of the 12 patients showed a degree of relapse at 3 months.

One should be cautious of the potential for inflated effect sizes in early trials, particularly when the sample size is small. That all patients showed some improvement in their depressive symptoms for up to 3 weeks after treatment could be suggestive of an expectancy bias. It may also be relevant that most patients in this trial were self-referring and, thus, actively sought this treatment. Psychedelics are known to promote suggestibility,[28] which might have further enhanced positive outcomes. Future double-blind randomised controlled trials could address the role of expectancy and suggestibility by measuring and controlling these variables. For example, patients could be asked about their pre-treatment expectations, suggestions could be controlled between conditions, and outcomes from self-referred patients could be compared with those from patients referred via clinicians. From a more pragmatic perspective, if expectancy or suggestibility are found to be influential in the context of psychedelic therapy, they could be treated as exploitable components of the treatment model rather than confounding variables.

Serotonergic antidepressants have been found to downregulate the primary receptor target of psilocybin (the 5-HT_{2A} receptor) and attenuated subjective responses to psychedelics have previously been reported in individuals chronically medicated with serotonergic antidepressants.[29] Thus, patients may be required to withdraw from concurrent antidepressant medication before receiving psilocybin and this should only ever be done with care. In conclusion, we sought to assess the safety and tolerability of psilocybin plus psychological support in patients with unipolar treatment-resistant depression. Our findings support the feasibility of this approach and the magnitude and duration of the post-treatment reductions in symptom severity motivate further controlled research. Psilocybin has a novel pharmacological action in comparison with currently available treatments for depression (ie., 5-HT_{2A} receptor agonism) and thus could constitute a useful addition to available therapies for the treatment of depression.

Contributors

RLC-H and DJN designed the study and RLC-H wrote the report. RLC-H coordinated the study, and collected and analysed the data. MBo was the lead psychiatrist on the trial. MBo, JR, CMJD, DE, and MBl provided psychological support for the patients. All authors critically revised the report or contributed important intellectual content.

Declaration of interests

DT has received research funding and lecture honoraria from Servier, and lecture honoraria from Lundbeck. The other authors declare no competing interests.

Acknowledgments

This study was funded by an MRC clinical development scheme grant (MR/J00460X/1). MK was supported by the Beckley Foundation and this work was carried out as part of the Beckley/Imperial Research Collaboration. The research was carried out at the NIHR/Wellcome Trust Imperial Clinical Research Facility. We would like to thank Robert Sullivan (Meridian West London, London, UK) for provision of high-quality audio equipment for the dosing sessions.

1.1. Aim of study

Our long term objective is to test the efficacy of psilocybin as an intervention for treatment-resistant major depressive disorder[31] but the primary objective of this pilot study is to optimise the protocol for the administration of oral psilocybin in this patient group. The knowledge and experience gained from this pilot study will be used to inform a subsequent randomised control trial (RCT) that will evaluate the anti-depressant properties of psilocybin. A secondary aim of the pilot is to use functional magnetic resonance imaging (fMRI) to try and identify how psilocybin affects brain activity before and after the psilocybin intervention.

1.2 Background of the study

This MRC-funded study is designed to optimise the procedures for a subsequent RCT of psilocybin as an intervention for treatment-resistant depression. The burden of depression is severe and increasing. Preventing relapse is a major challenge in depression; first line medications can decrease symptom severity but large numbers of patients fail to respond. Psilocybin is a naturally occurring compound that is structurally similar to the endogenous neurotransmitter serotonin. It had a brief history of use in psychotherapy in the 1960s but this was cut short for political reasons before its efficacy could be properly assessed. In recent years, a growing number of studies, including our own, have shown that psilocybin can be safely administered to human subjects[7] and there are now consistent reports of persistent improvements in well-being after just single exposures to psilocybin[12 10, 14].

2. Project outline

2.1 Main study design

This pilot study will involve 20 patients meeting DSM-IV criteria for major depression of a moderate to severe degree (17+ on the 21-item Hamilton Depression Rating Scale, HAM-D) that have failed to clinically respond to at least two different classes of antidepressant drug treatment (adequate dose, compliance and minimal duration of 6 weeks[31]) within the current episode. The main objective of the pilot study will be to establish feasibility and optimise procedures for a subsequent randomised clinical trial. The primary outcome of this pilot study will be the intensity of the subjective effects of orally administered psilocybin in this patient group. All 20 patients will receive the active drug psilocybin in two oral doses: a low (tester) dose and the other a high (active) dose 7 days apart. The doses that will be used in this study have been chosen based on previous research on the subjective effects of orally administered psilocybin[10-12, 14, 19, 35] and through discussions with leaders in the field that are currently working with oral psilocybin in clinical trials, including those involving patients with symptoms of depression.

Optimum doses for this study will be those that produce subjective effects of an appropriate intensity. To determine this, we will use a standard rating method; namely, patients provide a verbal rating of the intensity of subjective effects on a rating scale from 0 to 10, with 0 equalling 'no effects' and 10 equalling 'extremely intense effects'. Based on the previous literature and discussions with relevant experts, we have determined that 10mg (low dose) and 25mg (high dose) will provide effects of an appropriate intensity for this study. More specifically, it can be predicted that 10mg will produce effects rated 4-6/10 for intensity and 25mg will produce effects rated 7-9/10 and the pilot study will test this. Doses of 30mg psilocybin have been administered to healthy volunteers and patients suffering from anxiety and depression in previous trials (mostly individuals with no previous experience with psychedelic drugs) without major complications. Therefore, the proposed maximum dose (25mg) falls within this safe range. Please see the dosing algorithm below for how the low and high dose may be changed depending on the responses of the first 6 patients. The intention of the low/high dosing protocol is to give patients an initial low dose to enable them to have an impression of the drug effects at an attenuated intensity. We believe this to be a cautious and sensible approach. Thus, on the second dosing day patients will have an improved understanding of the procedure, some idea of the drug's effects and will be habituated to their surroundings and research team, all of which will augur well for receiving a higher active dose of the drug.

There will be around 11 days from screening to the first dosing session to allow the analysis of screening data (e.g. blood tests) to determine eligibility and enable contact to be made with their GP and/or mental health practitioners. Eligibility will be ascertained by the study psychiatrist who will thoroughly screen all patients to identify and confirm the presence of treatment-resistant major depression. Supporting information from relevant mental health professionals and general practitioners will be obtained prior to entry into the trial to confirm diagnosis and ensure that all patients meet the inclusion criteria.

The procedure for recruitment will be as follows: the patient's immediate care team will be made aware of the study (see below are the improved access to psychotherapy, IAPT, scheme) and will identify a patient and ask them if they are willing to be contacted by us. The primary caregiver will then inform us of their patient's interest and will provide a contact telephone number and/or email. The patient will be issued with an A4 summary sheet containing a brief summary of the study and our contact details. After the patient has initiated contact with us, we will inform them about the nature of the study and organise an appropriate time for an initial telephone screen. We will ask the patient if we can contact their GP/psychiatrist (this will be done via an email using a standard letter) and we will ask the patient to provide us with a letter of consent for us to do this. If the patient appears to be eligible (post-telephone screen and post-contact with their GP/psychiatrist), a date for the first screening visit will be arranged.

Typically, a patient would be screened on a Monday, scanned on a Friday and dosed the following Thursday. There will be 1 week from the final dosing session to the final formal follow-up assessment. Patients will be in the study for 26 days in total, see section 8, study time line, after which they will be allowed treatment as usual.

All patients will be contacted at regular intervals in the period following dosing to prompt them to complete the rating scale Quick Inventory of Depressive Symptoms. This will provide an indication of whether their depression has responded to psilocybin. The criteria for determining response will be a reduction of 25% in the (QIDS)[30] scores from baseline (screening), and remission will be scores of ≤5 on the QIDS[29]. Patients will be assessed remotely (i.e. electronically completed QIDS) for six months at which point the study will end.

In total, patients will be required to make at least 6 visits:

Visit 1/day 1: Screening and initial meet with the research team that will supervise the dosing
Visit 2/day 5: Scan 1 in IMANOVA followed by preparation/practice session with therapy team in CRF
Visit 3/day 11: Dosing session 1: low-dose psilocybin (10mg or 15mg) + post-session debrief
Day 12: Telephone follow-up
Days 12-17: remote QIDS
Visit 4/day 18: Dosing session 2: high-dose psilocybin (25mg ±5mg) + post-session debrief
Visit 5/day 19: Follow-up 2 and scan 2 in IMANOVA
Days 20-25: remote QIDS
Visit 6/day 26: Follow-up 3 (primary end point)
Day 32/week 5 (2 weeks post-dose): remote QIDS
Day 39/week 6 (3 weeks post-dose): remote QIDS
Day 53/~ month 2 (5 weeks post-dose): remote QIDS
Day 81/~month 3 (9 weeks post-dose): remote QIDS
Day 165/~month 6 (21 weeks post-dose): remote QIDS

Post-day 26, when we contact patients to request the completion of the QIDS, we will also ask them the open-ended question of whether they have anything to report in terms of persistent effects, whether positive or negative.

We will contact patients daily via telephone, email or text from day 12 to day 26 and thereafter on week 5, 6 and 8, and months 2, 3 and 6, to prompt the electronic completion of the QIDS[30]. Each patient will be issued with a study diary at screening and this will include all the important dates when they are expected to visit the study centre and to complete QIDS.

We may ask to see a patient before the follow-up visit on day 26, or after completion of the study, if adverse events are reported. On dosing days, we will also insist that patients be accompanied home by a friend or family member who can supervise and ensure that they are safe when returning home. We will ask for this person's contact details so that we can contact them if we have any difficulties contacting the patient him or herself. Both the patient and their 'chaperone' will be encouraged to contact us should any problems arise, particularly those that are felt to be attributed to the study intervention. In this way, any concerns in the immediate period or thereafter can be easily brought to our attention. We will be monitoring the patient's response in the ensuing weeks remotely via the QIDS. However, if we have any concerns about their mental state, we will liaise with their GP and/or mental health practitioners who may implement appropriate interventions if they deem fit. If the patient cannot nominate a significant other to accompany them home safely after a dosing session, a member of our study team will do this.

It will **not** be necessary for patients to withdraw from their antidepressant medication or psychological therapy when entering the study, since withdrawal may exacerbate depressive symptoms, and it will be informative to know whether psilocybin can be effective as an add-on to primary interventions. If a patient does decide he/she would like to withdraw from their medication, it will be necessary for them to be medication-free for at least 4 weeks prior to receiving their first dose of psilocybin. There will be 26 days from entry into trial (screening, **visit 1**) to the final follow-up visit (**visit 6**), after which patients may return to their normal treatments if they so wish.

The 4 week washout period should prevent any sudden exacerbation of symptoms during the study itself. However, if after withdrawal, symptoms show a marked increase at any point, we will discuss with the patient and their GP or consultant whether the patient should withdraw from the trial so that previous medications can be resumed or new ones given.

Secondary outcome measures in this study will be the mean change in QIDS scores from pre-dosing baseline at day 1 (**visit 1**) to follow-up at day 26 (**visit 6**, 1 week after the final dosing session). The QIDS is preferable to observer-rated scales such as the HAM-D because it measures internal states, is more sensitive to treatment effects, and covers more of the diagnostic criteria for depression[30]. The Montgomery and Asberg Depression Rating Scale (MADRS[18]) and HAM-D[32] will also be carried out at screening (**visit 1**, day 1), follow-up 2 (**visit 5**, day 19) and follow-up 3 (**visit 6**, day 26).

The HAM-D and MADRS ratings will be performed by clinicians with experience in its use. Assessors will not be directly involved in the dosing sessions. We have identified 1 primary assessor plus a substitute. A single patient will have the same assessor throughout the trial.

Additional outcome measures completed will include the MADRS, HAM-D, Beck depression inventory (BDI), global assessment of functioning (GAF[33]), Beck Anxiety Inventory (BAI[34]), Dysfunctional Attitudes Rating Scale (DARS[2]), the NEO personality inventory (NEO-PI[17]), Peters 21-item delusional inventory (PDI[25]), the Ruminative Responses Scale (RRS[28]), the dynamic emotional expression recognition task (DEER-T)[26], cued autobiographical memory task (AM-T)[37], Spielberger's Trait Anxiety Inventory (STAI), the Positive and Negative Symptoms Scale (PANSS), Snaith Hamilton Anhedonia Pleasure Scale (SHAPS), the Life Orientation Task (LOT-R), the Tellegen Absorption Questionnaire (Tellegen), the 5-Dimension Altered States of Conscious Scale (5D-ASC), the Psychotic Symptoms Inventory (PSI) and the Strunk Prediction of Future Life Events (POFLE) and Prediction of Personality Characteristics (PC) task. With the exception of the 5D-ASC, these assessments will all be carried out at screening and during the final follow-up visit on day 26. The SHAPS, LOT-R will be carried out at screening and repeated on day 19 and 26. Visual Analogue Scales (VAS) and the 5D-ASC will be used to measure subjective states during the dosing sessions and electronic versions of the QIDS will be completed daily in the 2 weeks following the first dosing session, plus also at week 5, 6, 8 and month 3 and 6. With prior consent, we will also send a patient's significant other a small number of self-constructed questions at day 26 (or 8 days after the second dosing session) to enquire whether they have noticed any changes in the patient's behaviour since the intervention. The significant other will also complete a brief questionnaire on the patient prior the first dosing session.

3. Basic safety and scientific background

The LD50 of psilocybin in rats is 280mg/kg[24]; thus, in terms of toxicity, its margin of safety is very large. We intend to give no more than 25mg. Psilocybin has been given to several hundred patients and volunteers in modern studies. In a thorough review of dosing sessions in 110 healthy subjects, dysphoric experiences/bad trips were rare and dose-dependent and there was no evidence of subsequent drug abuse, flashback phenomena or prolonged psychoses[27, 35]. Consistent with magic mushrooms user reports, the majority of subjects described their experiences as enriching, insightful and beneficial - but not something they would regularly repeat. Psilocybin is not habit forming in animals[27] or humans. We recently asked a large sample of experienced drug users to rank the relative harms and benefits of 11 of the most widely used recreational drugs in the UK[4]; users ranked magic mushrooms as the least harmful and one of the most beneficial drugs. The most commonly cited benefits were facilitated psychological insight and improved well-being. In a separate survey, without being explicitly cued, 5% of 503 magic mushroom users reported that magic mushrooms had alleviated their depressive symptoms, and 3.6% of 247 ketamine users reported this for ketamine[6]. Ketamine is currently being trialled for treatment resistant depression, with evidence of an impressive short-term efficacy ([39, 1]) but our survey results imply that psilocybin is safer than ketamine - and at least as effective.

Reports from the 1960s on the use of psilocybin in psychotherapy indicate clear benefits over harms[13]; however, these studies suffer from a lack of experimental control and standardised assessments. More recently, pilot studies have tested the efficacy of psilocybin in OCD[19] and anxiety related to terminal cancer[14]: In the former study, short-term reductions in compulsive symptoms were reported by all of the patients. In the latter study, trait anxiety was significantly decreased 1 and 3 months post session and depression scores were significantly decreased at 6 months. No clinically significant adverse events were observed in either study. In a large sample of healthy volunteers, orally administered high dose psilocybin induced mystical or spiritual-type experiences in over 60% of subjects[11]. Sixty seven percent rated their experience as either the single most meaningful experience of their lives - or among the top five. In a follow-up after 14 months, 64% of the sample maintained that the acute experience had led to a significant improvement in their sense of well-being or life satisfaction[12].

In the last two years, we have completed one pilot study[7], two fMRI studies[3] and one MEG study involving psilocybin infusion. We have carried out 54 dosing sessions in total and have seen no adverse events. Infused during scanning so to capture the transition from normal waking consciousness to the drug state, we found significant decreases in CBF and brain activity after psilocybin infusion and no increases in any region. It is important that the most consistent regional deactivation after psilocybin was in the medial prefrontal cortex (mPFC), a region that is consistently hyperactive in depression[8]. Medial prefrontal activity correlates with rumination[9] and symptom severity in depression[38], and is highly predictive of relapse[9]. Successful treatment with a variety of interventions, including ECT, SSRIs, cognitive behavioural therapy, sleep-deprivation, mindfulness meditation, and placebo, all normalise mPFC activity[8].

4. Study design

4.1. Primary outcome measure

Patient's ratings of the subjective intensity of psilocybin's effects, rated on a 0-10 scale, with 0 equally 'no effects' and 10 'extremely intense effects'.

4.2. Volunteers

Sample size: 20 patients
Males & females
18+ years old.

We will aim to recruit a similar number of male and female patients. Patients will be at least 18 years of age with must have an acceptable level of physical health as determined by a medical screening that will include: routine blood tests, ECG, blood pressure and heart rate, neurological exam and psychiatric assessment (MINI). We will take and store a blood plasma sample at screening for genotyping and baseline Brain Derived Neurotropic Factor (BDNF) levels, a marker of neurogenesis. Patients with cardiovascular abnormalities, epilepsy, personal or family histories of psychosis or psychotic symptoms (including mania), or histories of suicide attempts, will not be allowed to participate. As in previous trials, we will include patients who have previous experience with psychedelic drugs, although it is anticipated that most will be 'psychedelic-naïve'. All patients will have a good command of the English language. Patients will have HAM-D scores of at least 17, and will have failed at least two classes of antidepressant in the current episode. Women must not be pregnant or breast-feeding and appropriate use of contraception is mandatory.

4.2.1. Screening procedure

1. Informed consent
2. Full history-taking and physical examination
3. Psychiatric assessment (MINI)
4. Routine Blood Screen and sample
5. ECG
6. Urine drug screen
7. Height & weight measurements
8. Breathalyser
9. Completion of Clinician administered rating scales (HAM-D & MADRS)
10. Completion of secondary outcome measures as detailed in 2.1

4.2.2. Inclusion criteria

1. Major depression of a moderate to severe degree (17+ on the 21-item HAM-D).
2. No improvement despite two courses of antidepressant treatment for adequate duration (6 weeks minimum) within current episode[31].
3. No MR contraindications.

4.2.3. Exclusion criteria

1. Current or previously diagnosed psychotic disorder.
2. Immediate family member with a diagnosed psychotic disorder.
3. Medically significant condition rendering unsuitability for the study (e.g., diabetes, epilepsy, severe cardiovascular disease, hepatic or renal failure etc).
4. History of suicide attempts.
5. History of mania.
6. Blood or needle phobia.
7. Positive pregnancy test at screening or during the study.
8. Current drug or alcohol dependence.
9. Allergy to gelatine or lactose.
10. Lack of appropriate use of contraception.
11. Breast-feeding.

4.2.4. Withdrawal Criteria

1. Withdrawal of Consent.
2. Development of concurrent physical illness that necessitates their removal from the trial.
3. Deterioration of mental health warranting additional interventions and support.
4. Dependent or problematic alcohol and illicit substance use.

GPs and all pertinent health professionals will be informed of their patient's involvement in the study and will be encouraged to voice any misgivings or reservations they have about their patient entering the study or continuing with it once it has begun. On entering the study, should there be any deterioration in the patient's physical or mental health that may compromise their ability to continue in the trial, then we will reach an informed decision, once we have contacted the relevant health professionals, about whether the patient should continue in the study. This will all be done in discussion with the patient and the extended research team. Since we will be following the patient's progress in the period after dosing, we will be in a position to determine whether any added support or treatment is required should the patient's mental health deteriorate. Any information that comes to light during the study will be communicated to their main health professional in the community who will be in the best position to provide treatment if they consider it necessary.

5. Regulatory Issues and informed consent

5.1 Ethics Approval

The study will be conducted according to the revised declaration of Helsinki (2000), the International Committee on Harmonisation Good Clinical Practice guidelines and NHS Research Governance Framework. Ethics and R&D approval will be obtained.

5.2 Consent

Consent to enter the study will be sought from each participant only after a full explanation has been given, information sheet given and time allowed for consideration. Signed participant consent will be obtained for each patient. It is the right of the patient to refuse to participate without giving reasons and this will be respected. All patients are free to withdraw at any time from the protocol interventions without giving reasons and without prejudicing their further treatment.

5.3 Confidentiality

Patient's identification data will be required for the registration process. The research team will preserve the confidentiality of patients taking part in the study.

5.4 Audits and Inspections

The study may be subject to inspection and audit by Imperial College London and/or Imperial College Healthcare NHS Trust under their remit as sponsor and other regulatory bodies to ensure adherence to GCP. Prof Alan Young of Imperial College will Head a data monitoring committee for this study which will utilise the Inform System of Imperial College.

5.5. Monitoring

Any trial-related monitoring including audits and regulatory inspections will be permitted and direct access to source data and documents will be provided.

6. Patient recruitment strategy

Primary recruitment will be via referrals from mental health practitioners working in the field who have knowledge of the trial and feel that their patients fulfill the inclusion criteria (see below re the IAPT scheme, which will serve as our primary source of recruitment). This study will be adopted by the Mental Health Research Network (MHRN). Professor David Nutt sees patients through the Central & North West London Trust and Prof Steve Pilling via the Camden and Islington Trust (http://www.candi.nhs.uk/): both will act to encourage referrals to the study and the latter will be our primary source of referrals. We have strong links (through Steve Pilling) with the Improvement of Access to Psychotherapy Treatments (IAPT) scheme which runs out of the Camden and Islington Trust and who see many treatment-resistant depressed patients fitting this study's entry criteria. This will be our primary source of recruitment.

We will also liaise with fellow mental health practitioners working in other London Mental Health Trusts and mental health practitioners working in Oxford (Oxford Health Foundation NHS Trust) and Bristol mental health Trusts (Avon & Wiltshire Mental Health Partnership) to assist recruitment if necessary. We may also recruit via word of mouth should any patients want to participate having heard or read about the trial in the media or otherwise. In each case patients will be thoroughly screened by the study psychiatrist to ensure that they comply with our inclusion criteria before entry into the trial. General practitioners will be contacted in every case to inform them of the details of the trial and to enquire whether they have any concerns about their patient entering the trial. Until we have confirmed the patient's background medical and psychiatric history, patients will not be allowed to enter the trial.

7. Drug specific ethical and safety considerations

Recent independent assessments of the harms of popular drugs of abuse, conducted by international experts[22, 23, 36] and experienced drug users[4, 20] have consistently rated magic mushroom as one of the least harmful recreational drugs. Commonly cited risks include: prolonged psychotic reactions, flashback phenomena/hallucinogen persisting perceptual disorder (HPPD), and bad trips. Prolonged psychotic responses are extremely rare in clinical studies with psilocybin (<1%[35]), even with very high doses[11], and none have been reported in modern studies or studies with patients[14, 19]. The risk of flashback phenomena is also minimal. Typically, flashbacks or HPPD refers to drug-like visual perceptual effects (e.g. 'trails' or geometric patterns) occurring when no drug has been taken. The two largest surveys on this phenomenon found that very few psychedelic drug users (3-4%) report perceptual changes that are distressing to them[6]. There have been no cases of flashback-like symptoms occurring in modern clinical studies with psilocybin[35] - even with very high doses[11].

Negative acute psychological experiences or 'bad trips' do occur more frequently however, but they are strongly dose-dependent[10, 35]. In a sample of 36 healthy subjects given a high oral dose of psilocybin (30mg), 11 subjects reported strong anxiety at some point during their session[11]. However, the anxiety was short-lived in every case and no persistent negative mood effects were reported. Most of the subjects reported that their experience had been insightful and beneficial and this positive appraisal of their experience was sustained[12]. This is consistent with the claim that psychologically 'challenging' psychedelic drug experiences can be especially beneficial - if properly mediated. In our own work, dosing 40+ subjects with 2mg psilocybin IV, 30 of which took place in a spatially restrictive and noisy MRI scanner, anxiety scores were not significantly higher after psilocybin than placebo. No subjects showed panic or asked for their scans to be aborted. Patients with psychiatric vulnerabilities are thought to be more likely to experience bad trips, but we will strive to minimize this risk thorough psychological preparation, good patient-staff rapport and a positive environment. Bad trips are best managed psychologically[12 15] and administration of a benzodiazepine would only be used in cases of severe panic. Detailed protocols are available on the safe management of clinical research with psychedelics[15].

Note also that by administering a low dose of psilocybin in the first dosing session (10mg as the default low dose) we will be able assess tolerability prior to the administration of the higher dose (25mg). If a patient has a negative response to the 10mg dose, then he/she will be withdrawn from the trial. Moreover, the initial low dose may be useful therapeutically, allowing patients to accommodate to the effects of psilocybin prior to administration of a higher dose.

The summary of side effects associated with oral psilocybin on page 24 of the investigator's brochure will serve as the reference safety information for this trial.

7.1. Suicide and persistent adverse events

There have been no cases of increased suicidality in modern trails with psilocybin. The risk of suicide with placebo treatment is low (0.4% suicides and 2.7% attempts) and no higher than that with active treatments (0.7% and 3.4%[16]). The risk of suicide will be further minimized by excluding patients with histories of suicide attempts or planning. We will also give patients a study psychiatrist's and psychotherapist's contact number in cases of emergency. We have written a standard operating procedure for dealing with any adverse events and this is detailed below in section 14.

7.2 Definitions and reporting of Adverse Events & Reactions

1. **Adverse Event (AE)**: Any untoward medical occurrence in a patient or clinical trial subject administered a medicinal product and which does not necessarily have a causal relationship with this treatment.
2. **Adverse Reaction (AR)**: All untoward and unintended responses to a medicinal product related to any dose administered.
3. **Unexpected Adverse Reaction (UAR)**: An AR, the nature or severity of which is not consistent with the applicable product information.
4. **Serious Adverse Event (SAE) or Serious Adverse Reaction**: Any untoward medical occurrence or effect that at any dose i) results in death ii) is life-threatening iii) requires hospitalization iv) results in persistent or significant disability or incapacity.
5. **Suspected Unexpected Serious Adverse Reactions (SUSAR)**: any suspected adverse reaction related to a medicinal product that is both unexpected and serious.

Most AEs and ARs that occur in this study, whether they are serious or not, will be expected treatment-related toxicities due to the drugs in this study. The assignment of the causality will be made by the team including the principle investigator responsible for the care of the participant using the following definitions:

1. Unrelated: There is no evidence of any causal relationship.
2. Unlikely: There is little evidence to suggest there is a causal relationship and there is another reasonable explanation for the event.

3. Possible: There is some evidence to suggest a causal relationship however the influence of other factors may have contributed to the event.
4. Probable: There is evidence to suggest a causal relationship and the influence of other factors is unlikely.
5. Definitely: There is clear evidence to suggest a causal relationship and other possible contributing factors can be ruled out.
6. Not Assessable: There is insufficient or incomplete evidence to make a clinical judgment of the causal relationship.

Should any uncertainty exist regarding causality we will discuss within the team and farther afield with local clinicians and representatives. In the event that no agreement is made the MHRA will be informed of both points of view.

7.2.1 Reporting Procedures

All adverse events will be reported and depending on the nature of the event, the following reporting procedures will be followed:

1. Non serious AR/AEs: all such toxicities, whether expected or not, should be recorded as part of a case report and sent to the research team within one month.
2. Serious AR/AEs: Fatal or life threatening SAEs and SUSARs should be reported on the day that the research team is aware of the event. The SAE form requires nature of event, onset, severity, corrective treatment given, outcome and causality. Additional information will be sent within 5 days if the reaction has not resolved at the time of reporting. An SAE form will be completed within 24 hours.
3. SUSARs: a SAE report form will be completed by the staff at the site of where the adverse reaction occurred and sent immediately signed and dated to the research team with relevant treatment forms and anonymised copies of all relevant investigations. We will ensure that the MHRA, REC and the Sponsor are notified of all SUSARs occurring during the study according to the following timeline: fatal and life threatening within 7 days of notification and non-life threatening within 15 days. All investigators will be informed of all SUSARs occurring throughout the study. Any serious adverse events or reactions that are expected or otherwise will be reported to the sponsor immediately.

8. Study time line

Date	Event	Primary assessments	Duration
	Recruitment	QIDS (via web/email or telephone)	25 minutes
Visit 1 Day 1	**Screening at CRF**	BDI, BAI, QIDS, MADRS + HAM-D	4 ¼ hours
Visit 2 Day 5	Scan 1 at IMANOVA plus session with therapist	Brain function	5 hours
Visit 3 Day 11	**Dosing session 1 at CRF**	BDI, BAI + QIDS	8 hours
Days 12-17	Follow-up 1 & remote monitoring	QIDS (via email or telephone)	5 mins each day
Visit 4 Day 18	**Dosing session 2 at CRF**	BDI, BAI + QIDS	8 hours
Visit 5 Day 19	**Follow-up 2 at CRF +** scan 2 at IMANOVA	BDI, BAI, QIDS, MADRS + HAM-D	2 hours + 2 hours for scan
Days 20-25	Remote monitoring	QIDS (via email or telephone)	5 mins each day
Visit 6 Day 26	**Follow-up 3 at CRF**	BDI, BAI, QIDS, MADRS + HAM-D	2 ½ hours

9. Day 1, screening time line

Time	Event	Setting
9am	Subject arrives	CRF
9-9:30am	Informed consent	CRF
9:30-10:15am	Health assessment (inc. blood sample, ECG, blood pressure)	CRF
10:15-11:30am	MADRS, HAM-D and questionnaires	CRF
11:30am-1pm	MINI, open discussion and preparation for drug session	CRF
1:00pm	Patient returns home	CRF

10. Functional MRI

Patients will undergo 2 fMRI scans as part of this study, on the day after screening (day 5) and one on the day after the second dosing session (day 19). Patients will also be allowed an "acclimatisation" scan of ~ 5 minutes. This is an initial exposure to the MRI scan, to assess whether they can tolerate the scanning environment. The acclimatisation session will take place as part of the screening visit.

After entering the scanner, all volunteers will undergo a preliminary structural scan. They will be asked to relax. They may also be asked to carry out some simple psychological tasks (e.g. see[5]). Subjective ratings will be given. Pulse and blood oxygen levels will be measured throughout. Functional scanning will last approximately 50 minutes.

Set-up & structural scan	Functional scanning
~10 mins	~50 mins

Figure 1. Basic scanning protocol.

11. Day 5, Functional MRI and prep session with therapist

Time	Event	Setting
9:00am	Subject arrives	IMANOVA
9:00-9:30am	MR screen	IMANOVA
9:30am-10:30am	Scan	IMANOVA
10:30-11:30am	Questionnaires	IMANOVA
11:30am	Patient returns to CRF	CRF
12:00-3:00pm	Prep session with therapist Lunch break at 1pm	CRF

12. Follow-up

Time	Event	Setting
9am	Subject arrives	CRF
9-9:45am	Blood sample + behavioural tests	CRF
9:45-10:05am	HAM-D and MADRS	CRF
10:05-11:30am	Questionnaires	CRF

Follow-up visits will involve assessment via the HAM-D and MADRS and the completion of some questionnaires. The DEER-T and the AM-T will also be completed. A blood sample will be taken on follow-up 2.

13. Dosing and patient management

13.1. Dosing procedure

It is strongly advised that psychedelic drugs only be taken in a positive environment where the patient feels comfortable and relaxed and is supported by a psychotherapist or psychiatrist[15]. Efforts will be made to arrange the intervention room to promote relaxation without compromising medical safety. Mobile phones will be switched off during every session and efforts will be made to minimize unexpected interruptions.

Following patients' arrival, the study psychiatrist will determine whether the patient is in a medically fit state to proceed with dosing later and will carry out any physical examinations if this is indicated. This will be supplemented by measuring of vital signs and urine drug screen/breathalyser. Patients will have been strongly advised to refrain from alcohol approximately 24 hours prior to their arrival as alcohol may compound the effects of the drug and potentially interfere with its effects. Patients will be psychologically prepared for the experience at screening and we will simulate a dosing session in a pre-dosing preparatory session on the morning of each dosing day. We will advise the patient to surrender to the experience and relaxing music will be used to facilitate calm and a relaxed, accepting mind-set. We will caution patients to expect some anxiety, and they will be encouraged to let us know if they feel this. Consistent with published guidelines on managing psychedelic-drug sessions, patients will be advised to accept feelings of anxiety and to allow the experience to unfold naturally, without psychological resistance[15].

For each session, patients will sit in a reclined position with their head supported. They will be advised to close their eyes and relax.

13.2 Dosing parameters and algorithm

The patient will be provided with psilocybin capsules (x times 5mg capsules) which they will be requested to take with a glass of water to ensure the capsule is swallowed completely. The low dose will be 10mg or 15mg and this will always be administered in the first dosing session. The high dose will be 25mg (±5mg) and this will be given in the second session. This approach is motivated by safety and therapeutic considerations.

The desired effect for the initial low dose is mild/moderate subjective effects rated at 4-6/10 for intensity (0-10 scale with 0 equalling no effects and 10 extremely intense effects). Thus, although there is prior data to support the assumption that 10mg psilocybin will achieve this effect, if, after the first 6 patients have been dosed, it does not, then we will increase it to 15mg.

The desired effect for the 'high' dose is one that produces moderate-strong subjective effects rated 7-9/10 for intensity. Given the extensive literature on the effects of 25mg and higher doses of oral psilocybin, we do not anticipate it will need to be increased or decreased. However, if the desired intensity (rating of 7-9/10) is not observed in the first 6 patients, we will consider increasing it to 30mg or decreasing it to 20mg

for the subsequent 6 patients.
It is important to be clear that a decision to increase or decrease doses will be discussed by the study psychiatrist and the principal investigator (PI), with the PI making the final decision.

13.3 Patient management

The research team of Professor Roland Griffiths at John Hopkins University is experienced in supervising psilocybin sessions in healthy and patient populations. On their advice, we will 'check-in' with the patients at regular intervals (e.g. every 15-30 minutes). Otherwise, we will respond to the patient if they initiate contact with us. It is advised that active-intervention is kept to a minimum during the acute experience. The patient is encouraged to explore their own mental space. Simple guided imagery may be used to assist relaxation. The following is an example of a guided imagery script: "Imagine it is a beautiful sunny day ... you are walking on a beach ... the sky is blue ... the water is crystal clear ... you hear the sound of gentle waves lapping, as the light breeze caresses your skin ... the white sand feels warm on your bare feet and between your toes ... you are wearing flowing light clothes and breathing deeply, inhaling the smell of fresh ocean air ... a sense of freedom washes over your body ... you lie down and let your body sink into the warm soft sand ... you're completely relaxed ... you sink deeper and deeper into relaxation."

All sessions will be supervised by at least 2 individuals who will be introduced to the patient at screening. A medical doctor and study psychiatrist will be present at every dosing session and he/she will administer the drug or placebo. Typically, there will be an experienced psychotherapist and psychiatrist present at each session. Sessions will take place in a purpose built clinical research facility with extensive nursing and emergency support (the NIHR/Wellcome Trust Imperial Clinical Research Facility, **CRF**).

The effects of orally administered psilocybin last for approximately 5-6 hours peaking at 2-3 hours postadministration[10]. With the patient's prior consent, dosing sessions will be video and/or audio recorded and we may also video and/or audio record post-session interviews during follow-up visits. Patients will remain under supervision for at least 7 hours post-administration of psilocybin or until the effects have sufficiently subsided (as determined by the study psychiatrist). Taxis can be ordered to take patients home but they must be accompanied either by a member of the study team or by a significant other. Patients will be asked to text or call us when they return home. Twenty-four hour emergency contact numbers will be provided. Overnight care facilities are available in the clinical research unit in case of unexpected adverse events that require an overnight stay.

14. Standard Operating Procedure for managing adverse events

- Prior to administration of the drug we aim to fully prepare each participant to ensure that they are aware of what to expect. We will also ensure that they are met by all members of the research team and have the opportunity to visit the room in which the drug will be administered. Professor Griffith's team have used this approach and believe it to significantly reduce the possibility of any psychological adverse events following administration and serve to put patients at ease in the process. If patients know what to expect beforehand and are comfortable within their surroundings prior to receiving the drug, then this will reduce the risk of any untoward events.
- Patients will be escorted and chaperoned by a member of the research team at all times throughout their participation in the study and for the 3 to 4 hours during which they will be under the acute effects of psilocybin they will always be supported by a team member.
- The acute effects of the drug should be over within six hours following administration; however we will carefully monitor the patient for the duration of their stay at the study centre.
- Staff will be vigilant of any overly unusual behaviour, anxiety and paranoia. This will be brought to the attention of the research team in a discreet manner so as to not exacerbate the situation.
- Interpersonal exchanges that would be readily overlooked in a normal state of awareness may assume extreme and confusing meaning for persons under the influence of a psychedelic substance. Staff will be aware of this and adopt an open and non-judgemental manner, allowing the patient to speak freely without challenge.

- On occasion nursing staff may be called upon to monitor a patient but this will be rare as there will normally be sufficient personnel from the research team to perform this function.
- We do not envisage any serious side-effects from administration of the drug; however, patients may experience anxiety reactions or paranoid thoughts. These are likely to be short-lived and will be managed by psychological approaches such as reassurance and adopting a calm and supportive demeanour and by using behavioural techniques such as guided imagery.
- If the situation was to deteriorate even further, the research team may have to be more proactive in their attempts to reduce distress and this may require an assertive tone of voice and/or the laying of hands on the individual if their behaviour becomes erratic for example. This would only be done in an attempt to alleviate the patient's distress and maintain their and the research team's safety.
- In the unlikely event that a patient becomes behaviourally disturbed, medical personnel will be on hand to administer tranquillisation if necessary.
- Typical doses administered would be PO 5 - 10mg diazepam initially then titrated to effect.
- If such an adverse event was to occur, the study psychiatrist will closely monitor the patient at all times and in no circumstances will they be permitted to leave the unit until the psychiatrist is satisfied that they are in a fit state to do so.
- On discharge from the unit the patient will be reviewed which will encompass an assessment of their current level of risk and whether they have returned to their normal level of functioning. Once this is performed the psychiatrist in collaboration with the rest of the team will decide whether it is indeed safe for them to leave the unit and return home.
- Ideally, patients will be met by a family member or friend (the responsible other) after completing a dosing day so that this individual can accompany the patient home, supervise them and ensure their safety. If not possible a member of the research team will accompany them home to ensure their safe arrival.
- Overnight care facilities at the clinical research facility are available should these be required, especially if the drug effects have not completely abated and the patient needs ongoing supervision and/or monitoring.
- On discharge phone numbers for each member of the research team will be provided to the patient and their responsible other to ensure immediate contact if required. We will also have contact details for the patient and the responsible other so that we may contact them later that evening to check whether there are any issues that may have arisen.
- Appropriate follow-ups after dosing days are in place for monitoring the patient's status and mental health condition throughout the study and afterwards. We will therefore be able to detect and assess any delayed or persisting adverse events.
- Patients and family members will be encouraged to contact us should their mental or physical health deteriorate. Although our options of managing their current difficulties will be limited after the study is complete, we will be able to offer referral to the relevant services. If indicated, we will offer a further follow-up at the clinical research facility so that we can review the patient in person.

Should we have any concerns about the patient's mental health and safety during the study or follow-up and consider that a community intervention is necessary, we will contact the patient's primary caregiver i.e. their GP or primary mental health practitioner, to discuss to potentially implement this. It may well be that the study psychiatrist is required to make an urgent referral to the local crisis/home intervention service who may be called upon to assess the patient in the community to determine subsequent management. In an emergency situation, where the patient needs to have their mental health assessed and managed immediately, the local emergency duty team can be contacted requesting that an urgent mental health act assessment be convened to decide whether involuntary hospital admission is required.

15. Time commitments

Screening will take ~4 hours for consent, health and psychiatric assessment.
Scanning will take ~2 hours, including ~1hr minutes in the scanner. This is followed by the prep session with therapist on which will take 2 hours. Thus, visit 2 will take ~4 hours.
Each dosing day will take ~8 hours.
Follow-up visit 2 will take ~2 hours with the addition of 2 hours for scanning and follow-up visit 3 will take 2 ½ hours.

16. Purchasing and storing drug

Psilocybin free-base will be purchased and made to Good Manufacturing Practice standards in accordance with Medicines and Healthcare Products Regulatory Agency (MHRA) regulations. The drug will be stored in a secure laboratory in a locked fridge. Home Office permission for possession and storage will be obtained.

17. Analysis

The primary outcome for the pilot study is the intensity ratings given during dosing and since there is no control condition, data can be analysed as we progress. T-tests will be run to compare the intensity of the low and high doses. Functional MRI analyses will include: resting state functional connectivity, changes in CBF from baseline and activation to a simple psychological task. We expect that approximately two-thirds of the patients will agree to fMRI scans. With a sample of approximately 8 we may only be able to present preliminary findings at this point but of course, the fMRI scanned sample will increase with the occurrence of the RCT.

18. Dosing day timeline

Time	Event	Setting
9:00am	Subject arrives	CRF
9:00-9:30am	Brief assessment including vital signs/UDS/alcohol test	CRF
9:30-10:30am	Patient prepared and relaxed (music)	CRF
10:30am	Administration of drug	CRF
10:30am-4:30pm	Acute drug experience	CRF
4:30-5:30pm	Thorough debriefing + questionnaires	CRF
5:30pm+	Patients assessed for suitability to return home	CRF

The dosing day timeline will be subject to adaptation as we proceed but we will not keep patients at the study centre for longer than is necessary to carry out procedures although on occasion we may be obliged to request them to stay longer or overnight to ensure their safety.

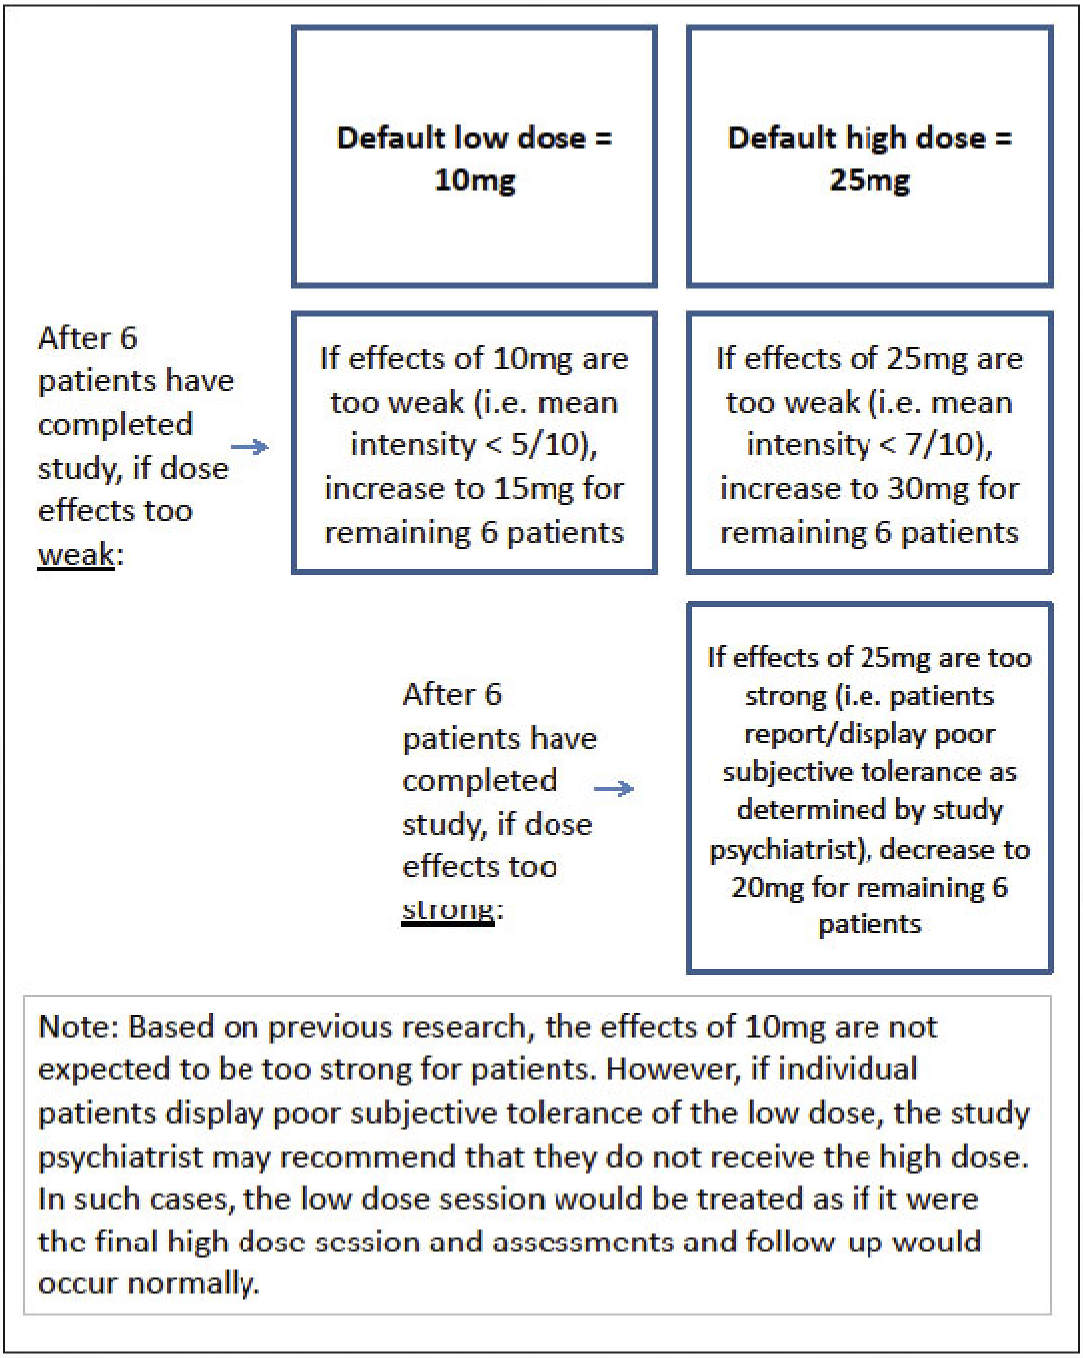
19. Monitoring

The study will be monitored internally by the Centre for Neuropsychopharmacology, through the Trust via InForm and it may also be audited by the MHRA and imperial JRCO.

20. IMP details

Psilocybin freebase (GMP) will be supplied by THC-pharm© (Frankfurt, Germany) with a certificate of analysis detailing purity and GMP quality. The psilocybin will be exported to Prof Val Curran of UCL who holds the necessary Home Office (HO) License for Schedule 1 drugs. Following HO guidelines, Prof Curran will transport the psilocybin to the Guy's and St Thomas' (GSTT) manufacturing pharmacy who also hold a HO License for Schedule 1 drugs. GSTT will weigh and encapsulate the product in accordance with GMP guidelines. Following HO guidelines for transport of Scheduled drugs, the psilocybin will then be transported to Prof Ilan Rabiner of Imanova, who also holds the required HO license. When a patient is to be dosed with psilocybin, Imanova will dispense the IMP to the study psychiatrist. The IMP will be given a shelf-life of 12 months. Storage conditions are light-protected and room temperature. Previous data has shown that psilocybin is stable for at least 6 years when stored under these conditions[21].

21. Dosing algorithm



Default low dose = 10mg

Default high dose = 25mg

After 6 patients have completed study, if dose effects too weak: →

If effects of 10mg are too weak (i.e. mean intensity < 5/10), increase to 15mg for remaining 6 patients

If effects of 25mg are too weak (i.e. mean intensity < 7/10), increase to 30mg for remaining 6 patients

After 6 patients have completed study, if dose effects too strong: →

If effects of 25mg are too strong (i.e. patients report/display poor subjective tolerance as determined by study psychiatrist), decrease to 20mg for remaining 6 patients

Note: Based on previous research, the effects of 10mg are not expected to be too strong for patients. However, if individual patients display poor subjective tolerance of the low dose, the study psychiatrist may recommend that they do not receive the high dose. In such cases, the low dose session would be treated as if it were the final high dose session and assessments and follow up would occur normally.

The link between use of psychedelic drugs and mental health problems

The March issue of *Journal of Psychopharmacology* included a study of the relationship between use of psychedelics (defined as lysergic acid diethylamide (LSD), psilocybin, and mescaline) and mental health problems (Johansen and Krebs, 2015). The data on 135,095 adult US citizens participating in the National Survey on Drug Use and Health (NSDUH) between 2008 and 2011 were obtained from a freely available database (http://oas.samhsa.gov/nsduh.htm, accessed 8 April 2015). The paper is a follow-up of a similar paper by the same authors on NSDUH data between 2001 and 2004 (Krebs and Johansen, 2013). For their analyses in the most recent paper, the authors distinguished between 19,299 individuals (13.4% of the study population) who reported lifetime use of psychedelic drugs, and the remaining group of individuals who did not report use of psychedelic drugs. Individuals were also asked about a range of mental health problems, and if they had been in contact with mental health service during the previous year.

The authors ran a series of logistic regression models to estimate the risk of having each of the mental health outcomes given lifetime use of psychedelic drugs. From these analyses, the authors concluded that use of psychedelics was not linked to mental health problems or suicidal behavior. In a recent issue of *Nature News*, the results from the Johansen and Krebs (2015) study were presented under the heading "No link between psychedelics and psychosis" (Cormier, 2015). In the following we will argue that the authors' conclusions in their latest paper are not substantiated by their results and will propose supplemental analyses to validate or potentially revise their conclusions.

According to Table 2 in the paper, 97.8% of the individuals reporting use of psychedelic drugs did also report lifetime use of cannabis, 71.3% reported use of cocaine, and 49.7% reported use of opiates. In the comparison group of individuals who did not report lifetime use of psychedelic drugs, the lifetime prevalence of use of other drugs was 36.0% for cannabis, 7.5% for cocaine, and 9.5% for opiates. From these figures, it is clear that the vast majority of users of psychedelic drugs have also used one or more substances other than psychedelic drugs. According to Table 2 in the paper, only 400 of the users of psychedelic drugs had never used cannabis, but a number of these had presumably used other drugs than cannabis. Notwithstanding this high degree of concomitant use of different types of drugs, the authors chose to include lifetime use of all other drugs than LSD, psilocybin, and mescaline as covariates in the logistic regression models of the relationship between psychedelic drugs and mental health outcomes.

From the numbers in Table 3 in the paper it is clear that the group of individuals who reported lifetime use of psychedelic drugs had two to three times higher prevalence of all mental health outcomes when not adjusting for lifetime use of other drugs. However, in the logistic regression analyses, correcting for all other types of drugs, the risk for having a mental health problem was not higher among psychedelic drugs users and the rest of the study population. In our view this is a typical example of over adjustment, a common, but relatively basic fallacy in epidemiological research (Rothman and Greenland, 1998). Since the authors did not report unadjusted risk estimates in their results section, not even as supplemental material, we have calculated odds ratios based on the prevalence figures presented in the paper. As shown in our new Table 1, use of psychedelic drugs was indeed associated with increased risk of mental health problems, e.g. a three times higher odds of being admitted to mental health hospital the previous year.

Given the high prevalence of concomitant drug use among the users of psychedelic drugs, it is difficult to use the NSDUH data to estimate the specific risk of psychedelic drugs for mental health problems in general. This argument is not related to the variance inflation factors, as mentioned by the authors in the statistical methods section of their paper, but to the effect sizes of their estimates. The results of the Johansen and Krebs (2015) paper cannot be generalized to the entire group of psychedelic drug users, and one might question the public health relevance of their findings. This comes in addition to other problematic factors in the paper, like selection bias. To validate their conclusion, we encourage the authors to report the exact number of individuals who had only used psychedelic drugs, and to present results of logistic regression models without adjustment or with different models for adjustment for lifetime use of other drugs.

Table 1. Association of psychedelic use with mental health.

	Ever used psychedelics	Never used psychedelics	OR (95% CI)	*p*
	N = 19,299	N = 115,796		
Serious psychological distress in worst month of past year

We have reported that in two large population surveys of randomly selected US adults psychedelic use was not associated increased risk of range of past year mental health outcomes, after adjusting for sociodemographic, psychological, and illicit drug use confounders (Johansen and Krebs, 2015; Krebs and Johansen, 2013). Nesvåg *et al*. (2015) present a table with crude odds ratios unadjusted for any confounders. These crude odds ratios do not take into account that people who have used psychedelics also have higher than typical rates of childhood depression, extremely traumatic experiences, illicit drug use, and other predictors for mental health problems (Johansen and Krebs, 2015; Krebs and Johansen, 2013). There are shared factors that predispose people to both illicit drug use and to mental health problems (e.g. Proal *et al.*, 2014). By considering use of other illicit drugs we are able, to some extent, to adjust for these other factors. In our original analyses, we also examined a stratified sub-sample of people without any past-year illicit drug use, to exclude mental health problems caused by direct drug effects (Johansen and Krebs, 2015; Krebs and Johansen, 2013).

Nesvåg *et al.* (2015) suggest that we look at mental health of people who had used psychedelics but no other illicit drugs. People who have used psychedelics and no other illicit drugs are not representative of the total population of people who have used psychedelics.

However, we have now repeated our analyses in both the 2008-2011 sample and the earlier 2001-2004 sample, excluding people who had ever used other illicit drugs, following the methods described previously (Johansen and Krebs, 2015; Krebs and Johansen, 2013). Results are shown in Table 2.

Table 2. Association between psychedelic (LSD, psilocybin, mescaline, peyote) use and mental health, excluding people with use of other illicit substances.

aOR: adjusted odds ratio

[a] Adjusted for age (11 categories, treated as a continuous variable), gender (male, female), race/ethnicity (white, Hispanic, black, Asian, Native American, Native Hawaiian or Pacific Islander, more than one), household income (less than $20,000, $20,000-$49,999, $50,000-$74,999, $75,000 or more), education (not high school graduate, high school graduate, some college, college graduate), married (unmarried, married), likes to test self by doing risky things (never, seldom, sometimes, always), and extremely stressful event (no, yes).

[b] Adjusted for depressive episode before age 18 years (no, yes) and above covariates, except for extremely stressful event.

Survey years 2001-2004

In the 2001-2004 sample, there were 192 adult respondents who reported using classical psychedelics (psilocybin, LSD, mescaline, or peyote) and no other illicit drugs (cannabis (marijuana), heroin, opiate pain relievers, cocaine, tranquilizers (benzodiazepines), sedatives (barbiturates), stimulants (amphetamine, methamphetamine, methylphenidate), MDMA (ecstasy), inhaled anesthetics (nitrous oxide, ether), alkyl nitrites (poppers), other inhalants (solvents, volatile chemicals), and PCP (phencyclidine)). In a logistic regression analysis adjusting for sociodemographic and psychological confounders, rate of symptoms of generalized anxiety disorder was increased with weak statistical significance in psychedelic users (adjusted odds ratio (aOR) = 3.9; p = 0.03). We failed to demonstrate an association between psychedelic use and increased rate of mental health treatment or symptoms of other psychiatric disorders, including major depressive disorder, panic disorder, posttraumatic stress disorder, mania, non-affective psychosis, and individual symptoms of non-affective psychosis including visual hallucinations. Notably, symptoms of non-affective psychosis were reduced in psychedelic users, but this was not statistically significant (aOR = 0.3; p = 0.17).

Survey years 2008-2011

In the 2008-2011 sample, there were 156 adult respondents who reported using classical psychedelics and no other illicit drugs. In logistic regression analysis adjusting for sociodemographic and psychological confounders, we found that people who had used psychedelics had increased rate of self-reported past-year outpatient mental health treatment (aOR = 3.2; p = 0.02), prescribed psychiatric medication (aOR = 2.8; p = 0.01), and physician diagnosis of depression (aOR = 3.4; p = 0.01), with weak statistical significance. Note, these are not independent outcomes, as people who seek psychiatric treatment would be expected to also have increased rates of psychiatric medication prescription and psychiatric diagnosis. In contrast, rate of self-reported needed but not receive psychiatric treatment was decreased but this was not statistically significant (aOR = 0.4; p = 0.25). We failed to detect statistically significant increases in rates of self-reported inpatient mental health treatment, physician diagnosis of anxiety disorder, or any symptoms of psychiatric problems: serious psychiatric distress, major depressive episode, suicidal thoughts, suicidal plans, or suicidal attempts.

Age onset of major depressive episode

Because the adjusted odds ratio of physician diagnosis of depression (but not symptoms of major depressive episode or suicide attempt) was increased amongst people who had used psychedelics but no other illicit drugs in the 2008-2011 sample, we examined reported symptoms of depression in more detail in this group by comparing age at first major depressive episode against age of first use and last use of "hallucinogens" (a broad, vaguely defined category which includes psychedelics). This data was not available in the 2001-2004 sample. Out of 22 respondents with available data on age at first major depressive episode, only two people experienced their first major depressive episode during the years they were using hallucinogens (plus one person reported first major depressive episode 8 years after first using hallucinogens but was missing data on age at last use of hallucinogens), of the remainder, nine people reported that their first major depressive episode occurred years before first using hallucinogens, and 10 people reported that their first major depressive episode occurred 3 years or more after last use of hallucinogens. Thus, data from this sample of people who have used psychedelic hallucinogens and no other illicit drugs does not suggest a temporal connection between psychedelic use and onset of major depressive episode.

Limitations

The confidence intervals on the adjusted odds ratios were large, so in most cases it is not possible to say with confidence if the associations are positive, negative, or neutral. It is possible that rates of both psychiatric symptoms and psychiatric treatment were increased in the psychedelic using group. It is also plausible, based on the 2008-2011 sample, that the select group of people who choose to try psychedelics but decline to try other illicit drugs might have an increased interest in psychology and mental health and be more predisposed than the general population to seek mental health treatment, even if they do not have increased rate of mental health problems. People who have used psychedelics and no other illicit drugs are unlikely to be representative of the total population of people who have used psychedelics.

The major difference between the 2001-2004 and 2008-2011 datasets is that exposure to an extremely traumatic event was available as a confounder only in the 2001-2004 dataset and childhood depression (major depressive episode before age 18) was available as a confounder only in the 2008-2010 dataset. Traumatic events and childhood depression were both correlated with psychedelic use and were both strong predictors of all indicators of mental health problems. It would be preferable to have a data set with data on both exposure to traumatic events and childhood depression, as well as other risk factors, such as history of childhood abuse, and family history of mental illness (McCann *et al.*, 2014; Proal *et al.*, 2014). Note, a study of 52 people hospitalized for first psychotic episode shortly after LSD use found that they had elevated rates of parental psychiatric hospitalization, similar to people with schizophrenia (Vardy and Kay 1983).

The statistical significance of all the "statistically significant" results presented here were weak ($p > 0.01$), and so should be considered with caution. When conducting multiple statistical tests, it is likely to have false-discovery findings simply by chance. None of these "findings" would be considered statistically significant if we adjusted for multiple tests (13 tests for the 2001-2004 sample, not counting the specific symptoms of nonaffective psychosis, and 11 tests for the 2008-2011 sample) using either the Bonferroni method (with alpha of 0.05) or the less stringent Benjamini-Hochberg method (with a false-discovery rate of 0.05) (Benjamini and Hochberg, 1995).

A cross-sectional population study cannot demonstrate causation. We looked only at the population level; it is possible that psychedelics could hurt some individuals and help others. For example, there are some reports of first-episode psychosis after taking psychedelics (Catts and Catts, 2010), but on the other hand there are also reports of sustained recovery from chronic paranoid psychosis in hospitalized patients following a single dose of psychedelics (Denber and Merlis, 1954; Denber, 1956). See the original articles for more limitations and discussion (Johansen and Krebs, 2015; Krebs and Johansen, 2013).

Comments

Overall, there is a lack of evidence that psychedelics increase the rate of mental health problems on a population level (Bonson, 2012; Catts and Catts, 2010). As Jorgen Bramness said in response to our population study of psychedelics and mental health: "The study shows, in agreement with previous studies, that we probably have exaggerated the danger of the use of psychedelics in general, and LSD in particular, at least if we are to judge on the basis of drug laws" (Tveito, 2013).

Data on mental health of psychedelic users is also available from communities where psychedelic use is legal and less stigmatized. A longitudinal case-control study found that people who had used ayahuasca (a South American psychedelic beverage containing dimethyltryptamine which is chemically similar to psilocybin) over 360 times each in legally-protected religious ceremonies scored significantly lower on all psychopathology measures compared to people who regularly participated in nonpsychedelic religious groups, both at baseline and at one year follow-up (Bouso *et al.*, 2012). A case-control study of Native Americans failed to find any evidence of cognitive or mental health deficits among people who regularly used peyote in legally-protected religious services compared to those who did not use peyote, and reported that total lifetime peyote use (mean 300 occasions, range 150-500) was associated with overall better mental health (Halpern *et al.*, 2005). A four-year observational study by a psychiatrist on a Native American reservation estimated the rate of serious adverse psychiatric reactions to peyote as 1 per 70,000 occasions of peyote use in legally-protected religious ceremonies, participants included people with schizophrenia and other mental illness (Bergman, 1971). In the Netherlands, where psychedelic psilocybin mushrooms are legally sold in shops, the rate of ambulance calls leading to hospitalization for acute psilocybin-related psychiatric problems or injury has been estimated at one hospitalization per 50,000 servings of psilocybin mushrooms sold (most cases involved alcohol and other drugs) (CAM, 2007). And out of 4 million attendees at large electronic dance music festivals in the Netherlands, there were only 35 visits to first-aid stations that involved psilocybin mushrooms (none required further medical attention) (Krul, 2011), demonstrating that legal sale of psilocybin mushrooms creates very few problems at "rave" festivals.

The most definitive way to determine adverse effects of psychedelics would be randomized controlled trials.

Recent randomized controlled trials of psilocybin of approximately 1000 doses in approximately 400 volunteers (screened for pre-existing mental health problems) have not reported any adverse emotional reactions lasting beyond a few weeks or any prolonged psychotic reactions (e.g. Studerus *et al.*, 2011). Likewise, clinical trials of LSD and mescaline from the 1950s-1970s are typically interpreted as showing low rates of prolonged problems (McWilliams and Tuttle, 1973). Studies from the 1950s-1960s of LSD and mescaline in people with schizophrenia and other serious mental illness generally reported that psychedelics can temporarily exacerbate pre-existing psychiatric symptoms during the drug effects, but with few or no prolonged adverse effects, and as noted above occasionally lasting remission from psychosis or other psychiatric problems. In the most commonly cited study of prolonged effects of LSD in people with schizophrenic, after 158 total administrations of LSD (dose up to 840 mcg) to 65 patients with chronic psychosis (hospitalized on average for 5 years) there were three instances of prolonged exaggeration of prior symptoms (no details) with onset soon after LSD (Fink *et al.*, 1966), but there was no control group and some of these patients would have been expected to worsen regardless of LSD.

The idea that psychedelics often cause lasting mental health problems or are otherwise "extremely dangerous" appears to have been based on case reports, rumors, "worst-case scenarios," politics, cultural biases, and outdated theories about the inherent dangers of "self-exploration," rather than epidemiological data (Johansen and Krebs, 2015; Krebs, 2015; Rucker 2015). In many ways the mid-20th century "moral panic" against psychedelics paralleled claims from previous generations that mental illness and suicide were caused by activities involving introspection, creativity, and fantasy, such as Christian mystical contemplation (from the influential psychiatrist Philippe Pinel, 1790: "the mind remains in a kind of imbecility during which they speak only of marvels and miracles") (Murat, 2014), reading fictional novels (from 1869: "Common novel-reading is a fearful evil... the safest rule is total abstinence"; from 1820: "his soul kindled into ardor at scenes of imagined bliss, which probably he will never realize, but which will only prepare his mind for bitter disappointment") (Crane, 1869; Dodge, 1820), masturbation (from 1834: "self-abuse" leads to over-stimulation, brain inflammation, insanity, and "mental decay") (Whorton, 2001), and jazz music (from 1921: "the effect of jazz on the normal brain produces an atrophied condition on the brain cells.... it is harmful and dangerous, and its influence is wholly bad") (Knowles, 2009). Restrictions on all these activities were enacted or proposed on pseudo-medical grounds. It was possible to point to case examples of, for instance, a young woman who read many books and then killed herself, and there is evidence that poets, jazz musicians, mathematicians, and other creative professionals do have higher rates of mental illness, but of course this does not demonstrate that these activities directly cause mental health problems (Kaufman and Paul, 2014).

Abstract - Psychedelic drugs have long been known to be capable of inducing mystical or transcendental experiences. However, given the common "recreational" nature of much present-day psychedelic use, with typical doses tending to be lower than those commonly taken in the 1960s, the extent to which illicit use of psychedelics today is associated with mystical experiences is not known. Furthermore the mild psychedelic MDMA ("Ecstasy") is more popular today than "full" psychedelics such as LSD or psilocybin, and the contribution of illicit MDMA use to mystical experiences is not known. The present study recruited 337 adults from the website and newsletter of the Multidisciplinary Association for Psychedelic Studies (MAPS), most of whom reported use of a variety of drugs both licit and illicit including psychedelics. Although only a quarter of the sample reported "spiritual" motives for using psychedelics, use of LSD and psilocybin was significantly positively related to scores on two well-known indices of mystical experiences in a dose-related manner, whereas use of MDMA, cannabis, cocaine, opiates and alcohol was not. Results suggest that even in today's context of "recreational" drug use, psychedelics such as LSD and psilocybin, when taken at higher doses, continue to induce mystical experiences in many users.

Keywords - LSD, MDMA, mystical experiences, psilocybin, psychedelic drugs, religious experiences

When taken in sufficient doses the psychedelic drugs LSD and psilocybin have been widely reported to elicit mystical or transcendental religious/spiritual experiences (e.g., Harris 2011; Griffiths *et al*. 2006; Hasler *et al*. 2004; Horgan 2003; Smith 2000; Bakalar 1985; Hofmann 1983; Pahnke 1969, 1963; Pahnke & Richards 1966; Watts 1965; Leary 1965; Maslow 1964). Insights into God or Ultimate Reality, transcendence of the personal ego, merging with the cosmos and undergoing transformative death and rebirth are common elements of the mystical experiences reported by many of those who have taken high doses of LSD or psilocybin. Such reports resemble in some respects the classical descriptions of self-realization or enlightenment arising from the mystical traditions of major religions such as Buddhism and Hinduism (Horgan 2003; Grinspoon & Bakalar 1979; Watts 1965; Suzuki 1957; James 1905).

Psychedelic drugs are potent direct serotonin agonists (Jacobs 1987) that can induce powerful activation of the cerebral cortex, especially the prefrontal region (Vollenweider *et al*. 1997). Although the peak in popularity of psychedelics, particularly LSD, was in the 1960s, psychedelic drugs are still taken illicitly today but the purposes of present-day use can be quite different from the motives of typical LSD users in the 1960s. Today psychedelics are often used to enhance sensory experiences at concerts and dance parties - in contrast to the ego-transcending or "mind-expanding" goals of most psychedelics users in the 1960s. This change is reflected in the typical unit doses of LSD available on the black market today, which are considerably lower than the typical unit doses available in the 1960s (Laing & Siegel 2003). Black market unit samples of LSD in both the U.S. and Europe in the 1960s often contained several hundred micrograms (see erowid.org/chemicals/lsd/lsd_history1.shtml), a dose range characterized as "strong" or "heavy" by the popular drug use information website erowid.org; by contrast in the past decade typical black market LSD unit doses averaged only about 50 micrograms (Hidalgo 2009; Laing & Siegel 2003), a dose range characterized by erowid.org as "light" and said to be well below the threshold for a revelatory mystical psychedelic experience (Stafford 1983). Moreover the most commonly used drug with psychedelic properties today is not LSD or psilocybin but MDMA ("Ecstasy"), which induces a mix of stimulant and mild psychedelic effects that are reported to be less intense and more controllable than those induced by "full" psychedelics such as LSD and psilocybin (Rushkoff 2001). LSD and psilocybin are often referred to as "entheogens," meaning "to awaken God within," whereas MDMA is often described as an "entactogen," meaning "to touch within" (Bravo 2001; Smith 2000), reflecting the differences between MDMA and "full" psychedelics.

Pahnke (1963) and Griffiths and colleagues (2006) demonstrated that a strong dose of psilocybin administered in a controlled, supportive experimental setting can induce profound mystical experiences in drug-naïve subjects, with self-reported transformative effects that for some have lasted decades (Doblin 1991). The present study examined mystical experiences in relation to illicit drug use among a sample of "recreational" psychedelic and other drug users. Given that psychedelic drug dose is said to be a crucial factor influencing whether an occasion of use is capable of catalyzing a transformational mystical experience, we expected to find that the usual dosage taken as reported by users for the full psychedelics LSD and psilocybin, but not MDMA or nonpsychedelic drugs such as cannabis, cocaine, opiates or alcohol, would be positively related to self-reported mystical experiences as well as to experiences of an "overwhelming" nature. Scores on the Depression Anxiety and Stress Scales (DASS-21) served as a control for the potential influence of mild psychopathology on such self-reports. In addition, self-report measures of specific life values and empathy were examined, as a previous cross-cultural study found that psychedelic drug users rated the life values of spirituality, creativity, concern for the environment and concern for others more highly than did nonusers (Lerner & Lyvers 2006), a difference which the authors speculated might be a result of mystical experiences in the former group. Mindfulness was also examined given the foundation of that concept in the mystical Zen Buddhist tradition (e.g., Maezumi & Glassman 2007).

Method

Participants

Participants were recruited online from members of the Multidisciplinary Association for Psychedelic Studies (MAPS) and those who visited its website (www.maps.org). MAPS is a nonprofit organization promoting research on potential medical and psychiatric applications of marijuana and psychedelic drugs. A monthly newsletter emailed to MAPS members in April 2011 contained a brief description of the online survey and a link to it. This information was also placed on the MAPS website. The total number of participants who completed the survey was 350, with 337 providing usable data. Among these 337 participants, ages ranged from 16 to 79 years (*M* = 29.12 years, SD = 12.14), and 68.5% were male. The majority (68%) reported having a university degree; 32% of participants were students, and 58% of participants were employed full-time.

Approval was obtained from the Bond University Human Research Ethics Committee prior to the commencement of the study. No incentive was offered for participation.

Materials

To commence the online survey administered via Survey Monkey, each participant had to read an explanatory statement which assured them of the anonymity of their data, and informed them of their right to withdraw from the study at any time without consequence. The following questionnaires comprised the survey.

Demographics and Drug Use Questionnaire

This measure was created for this study and asked for the participants' age, gender, education, occupation, and personal history of use of alcohol and illegal drugs including cannabis (marijuana), MDMA (Ecstasy), cocaine, opiates, LSD and psilocybin. Participants were asked to estimate their frequency of use on a six-point scale where 0 = "never," 1 = "rarely," 2 = "monthly," 3 = "fortnightly," 4 = "weekly," and 5 = "daily." They were also asked to estimate their usual dosage taken on a four-point scale where 0 = "none," 1 = "low dose," 2 = "common dose," and 3 = "strong dose." Participants were also asked if they had ever had an overwhelmingly intense experience of any kind - not necessarily drug induced but could include drug experiences - by ticking either "yes" or "no." For those who indicated they had used psychedelics, a question asked for the participant's motives for such use.

Mysticism Scale

This 32-item questionnaire (Hood 1975) contains items that ask participants about past mystical experiences (if any). The Mysticism Scale has been used in research on the psychology of religion (Spilka *et al*. 2003) but has only previously been applied to drug experiences by Griffiths and colleagues (2006), who used it to assess psychedelic drug (psilocybin) experiences. The Mysticism Scale yields a total score based on three dimensions of mystical experience: noetic quality (e.g., "I have never experienced anything to be divine," reverse-scored); introvertive mysticism (e.g., "I have never had an experience which I was unable to express adequately through language," reverse-scored); and extrovertive mysticism (e.g, "I have had an experience in which I felt everything in the world to be part of the same whole"). The items are rated on a nine-point scale ranging from -4 = "this description is extremely not true of my own experience or experiences" through 0 = "I cannot decide" to +4 = "this description is extremely true of my own experience or experiences." The psychometric properties of this scale have been reported to be sound (Reinert & Steifler 1993).

States of Consciousness Questionnaire

The SCQ (Griffiths *et al*. 2006) contains 100 items pertaining to states of consciousness and mood, but only the 43 items of the Pahnke-Richards Mystical Experience Questionnaire (*MEQ*; Pahnke 1969; Richards 1975) are scored, with the remainder being distractor items. The MEQ was used in Pahnke's 1966 Good Friday experiment as well as in the subsequent psilocybin study by Griffiths and colleagues (2006), the latter in the form of the SCQ as in the present study. The MEQ assesses experiences of internal unity, external unity, transcendence of time and space, ineffability, paradoxicality, sacredness, noetic quality, and positive mood. Participants rated each statement on a six-point Likert scale for degree of having experienced the phenomenon listed, from 0 = "not at all" to 5 = "extreme." A sample item is "sense of profound humility before the majesty of what was felt to be sacred or holy." Total scores can range from 0 to 215.

Balanced Emotional Empathy Scale

This scale (BEES; Mehrabian 1996) assesses one's perceived ability to identify and feel the emotions of others. Participants rate 30 items on a nine-point Likert scale where -4 = "very strong disagreement," 0 = "neither agreement or disagreement," and +4 = "very strong agreement" with each item. A sample item is "I am moved deeply when I observe strangers who are struggling to survive." Research has indicated that the BEES has good to excellent internal consistency, convergent validity and predictive validity (Mehrabian, Young & Sato 1988; Mehrabian & Epstein 1972).

Life Values Inventory

The LVI (Crace & Brown 1996) uses 42 items to measure 14 different life values that are rated for personal importance on a five-point Likert scale, where 1 = "almost never guides my behavior," 3 = "sometimes guides my behavior" and 5 = "almost always guides my behavior." The 14 life values are achievement, belonging, concern for the environment, concern for others, creativity, financial prosperity, health and activity, humility, independence, loyalty to family or group, privacy, responsibility, scientific understanding, and spirituality. Brown and Crace reported high test-retest reliability for the 14 life values ranging from .78 to .97. For the purpose of this study only creativity, spirituality, concern for the environment, and concern for others were examined, based on previous findings described earlier above (Lerner & Lyvers 2006).

Langer Mindfulness Scale

The LMS (Langer 2004) assesses the construct of mindfulness as practiced in everyday life. Participants rate 21 items in reference to their personal outlook on a five-point Likert scale where 1 = "strongly disagree," 3 = "neutral," and 5 = "strongly agree." There are four subscales, novelty-seeking, engagement, novelty-producing, and flexibility; as these have been found to load onto a single scale score, only the total score was used in the present study.

Depression Anxiety and Stress Scales

The DASS-21 (Lovibond & Lovibond 1995) is comprised of 21 items concerning negative mood states experienced in the past week, rated using a four-point Likert rating scale where 0 = "these statements did not apply to me at all," 1 = "applied to me some of the time," 2 = "applied to me a good part of the time," and 3 = "applied to me most of the time." There are three subscales, depression, anxiety and stress. Items include "I just couldn't seem to get going" (depression), "I found it difficult to relax" (anxiety) and "I found it hard to wind down" (stress). Normal scores for depression are 0-9, anxiety 0-7, and stress 0-14 (Lovibond & Lovibond 1995), with higher scores indicating psychopathology. The psychometric properties of this widely used measure are regarded as excellent (Crawford & Henry 2003).

Procedure

Participants completed the questionnaires anonymously online via Survey Monkey. Once they opened the link to the present survey on their computer, they first read the explanatory statement. Then, participants clicked "Next," which directed them to the demographics questionnaire. After the completion of this section, participants proceeded to the other questionnaires. Upon completing the last questionnaire, participants clicked "Finished," which brought them to a thank you and appreciation page.

Results

After removal of multivariate outliers and cases with substantial missing data from the dataset, 337 cases remained to provide usable data. Of these 337 participants, 99% reported having used alcohol, 58% reported having used cocaine, 40% reported having used opiates, 96% reported having used cannabis, 74% reported having used MDMA, 83% reported having used LSD, and 89% reported having used psilocybin. The very high proportions of the sample who reported having used cannabis and psychedelics was expected given the nature of MAPS as an advocacy group promoting potential beneficial applications of these substances. However, estimated self-reported frequency of drug use was low in this sample except for use of alcohol and cannabis. The most commonly reported frequency of use for alcohol was "weekly" (35%), whereas for cannabis the most commonly reported frequency of use was "daily" (44%). By contrast, "rarely" (less than monthly) was the most commonly reported frequency of use for cocaine, opiates, MDMA, LSD and psilocybin in this sample. Self-reported doses taken showed a broader distribution than frequency of use, although "common" was the most frequently cited dose level with frequencies ranging from 13% to 45% for this dose category; the exceptions were cocaine and opiates, for which the most commonly cited quantity was "none" (these drugs having the lowest proportion of users in the sample; see above). DASS depression, anxiety and stress scores were quite low in this sample, averaging only three or four out of a possible 21. Among those who reported having used psychedelics and provided motives for use, the most common self-reported motive for use was "mind expansion" (41%), followed by "spiritual" (25%), "curiosity" (13%) and "recreation" (7%), with the remainder citing "other."

Intercorrelations among the measures of interest were calculated and are presented in Table 1. Illicit drug doses were all intercorrelated as expected, such that self-reported use of higher doses of any one drug were associated with self-reported use of higher doses of other drugs as well. LSD dose was significantly positively correlated with scores on the Mysticism Scale, MEQ, and LVI Creativity. Psilocybin dose was significantly positively correlated with Mysticism and MEQ scores. The other illicit drugs (cocaine, cannabis, opiates, MDMA) showed only small to no correlation with any of the scales, and none with Mysticism or MEQ scores. Alcohol dose was significantly negatively correlated with BEES empathy scores and three of the five LVI values: environmental concern, concern for others, and spirituality. Participant age was significantly negatively related to all self-reported drug doses except cocaine, and significantly positively related to BEES empathy, LVI environmental concern and LVI spirituality.

Several of the scales were significantly intercorrelated in expected ways. For example, BEES empathy scores were positively correlated with LVI concern for others; LVI spirituality scores and LMS mindfulness were positively correlated with each other and with Mysticism, MEQ, BEES, and LVI concern for others, creativity and environmental concern; and the DASS scales were all intercorrelated as usual (e.g., Lyvers *et al*. 2010) although interestingly they did not significantly correlate with any other measure including drug use indices (see Table 1).

Hierarchical regression was used to assess predictors of the primary criterion measures of interest, i.e., Mysticism Scale scores and MEQ scores, examining the possible roles of LSD and psilocybin dose after controlling for demographic variables, mood variables, and self-reported doses of drugs other than LSD or psilocybin. In these regressions age, gender and education level were entered at step 1, followed by DASS depression, anxiety and stress scores at step 2, self-reported doses of alcohol, cannabis, cocaine, opiates and MDMA at step 3, and self-reported doses of LSD and psilocybin at step 4. For prediction of Mysticism Scale scores the regression model was only significant at step 4, $F(13, 291) = 2.79$, $p < .001$; the addition of psychedelic drugs at step 4 accounted for 11% of the variance in Mysticism Scale scores, $Fchange\ (2, 291) = 10.60$, $p < .0001$. The only significant drug predictors of Mysticism scale scores were LSD dose, $\beta = .23$, $p < .0001$, and psilocybin dose, $\beta = .13$, $p = .04$. No other predictors approached significance except for age at step 4 only, $\beta = .14$, $p = .02$. For MEQ scores as the criterion the results were very similar; again the regression model was only significant at step 4, $F(13, 291) = 3.12$, $p < .0001$, and the addition of psychedelic drugs at step 4 explained 12% of the variance in MEQ scores, $Fchange(2, 291) = 12.60$, $p < .0001$. The only significant drug predictor in the final model was LSD dose, $\beta = .26$, $p < .0001$, with psilocybin dose approaching significance, $\beta = .11$, $p = .07$, and age again significant at step 4 only, $\beta = .13$, $p = .03$.

Finally, among drug use variables, only use of drugs with psychedelic properties was significantly related to the report of having ever had an overwhelming experience. Among those who reported ever using LSD (n = 280), 89% responded "yes" to the question asking whether they had ever had an overwhelmingly intense experience of any kind, compared to only 68% of those who said they never tried LSD (n = 57), a significant association, $\chi2(1) = 15.81$, $p < .0001$. Similarly, among those who reported ever using psilocybin (n = 299), 88% reported having had an overwhelming experience versus only 59% of those who said they had never tried psilocybin (n = 37), again a significant association, $\chi2(1) = 21.61$, $p < .0001$. By contrast there was no relationship between use of the nonpsychedelic drugs alcohol, cocaine, opiates, and cannabis with having ever had an overwhelming experience, all $p > .20$; however use of MDMA, a drug with mixed stimulant and mild psychedelic properties, was significantly related to the report of an overwhelming experience, $\chi2(1) = 14.96$, $p < .0001$. Of those who said they had tried MDMA (n = 249), 85% reported having ever had an overwhelming experience compared to 72% of those who said they had never taken MDMA (n = 87). However, use of MDMA was strongly related to use of LSD, with 90% of those who reported ever using MDMA also reporting use of LSD versus only 61% of those who reported never using MDMA, $\chi2(1) = 41.00$, $p < .0001$; nearly identical results were obtained for self-reported use of psilocybin by those who reported use of MDMA versus those who did not, $\chi2(1) = 28.67$, $p < .0001$. Therefore the reports of overwhelming experiences by MDMA users may reflect their use of LSD or psilocybin rather than MDMA. In an attempt to assess this, MDMA use was examined in relation to reports of an overwhelming experience among the 15 participants who said they had never tried LSD or psilocybin, ten of whom reported never using MDMA versus five who reported MDMA use. In this subgroup there was no significant association between MDMA use and reports of an overwhelming experience, $\chi2(1) = 1.25$, $p =.26$, however given the very small size of this subgroup the lack of significance is not surprising. Of those who said they had used MDMA, three out of five reported having ever had an overwhelming experience versus only three out of ten of those who reported never using MDMA. By contrast among those 57 participants who reported never using LSD, psilocybin use was significantly related to reports of ever having had an overwhelming experience, $p < .01$; likewise among the 37 who reported never using psilocybin, LSD use was significantly related to reports of ever having had an overwhelming experience, $p < .05$.

Discussion

Results were in line with predictions for the two indices of mystical experiences, the Mysticism Scale and the MEQ, the variances of which were significantly explained by self-reported dose of LSD or psilocybin but not of other drugs. Furthermore the self-report of having ever had an overwhelming experience was significantly associated only with self-reported use of drugs with psychedelic properties, i.e., LSD, psilocybin and MDMA, although the latter association may reflect the extremely high overlap between MDMA users and users of the "full" psychedelics LSD or psilocybin in this sample. Mysticism Scale and MEQ scores were significantly highly positively correlated with each other and with all four LVI values (environmental concern, concern for others, creativity and spirituality) as well as with BEES empathy and LMS mindfulness, consistent with expectations based on the mystical traditions of Buddhism and other religions according to which such values, as well as mindfulness, can be lasting sequelae of mystical enlightenment. However, aside from a small positive correlation between self-reported LSD dose and LVI creativity, there were no significant relationships between self-reported dose of any illicit drug - including psychedelics - and the other LVI values tested, nor with BEES empathy or LMS mindfulness. Alcohol dose was negatively related to BEES empathy and LVI environmental concern, concern for others and spirituality.

The vast majority of the current sample of MAPS members and those who visited the MAPS website reported use of psychedelic drugs. This was expected based on the mission of MAPS, a nonprofit organization dedicated to supporting medical and psychiatric applications of psychedelic drugs as well as MDMA and cannabis. However the vast majority reported only "rare" (i.e., less than once per month) use of such drugs; 74% of LSD users said they "rarely" used LSD, 77% of psilocybin users said they "rarely" used psilocybin, and 69% of MDMA users said they "rarely" used MDMA. This was in contrast to cannabis users, 44% of whom reported "daily" use. Despite the low frequency of use of psychedelic drugs in the sample, self-reported psychedelic dose predicted scores on the two mystical experiences questionnaires as per expectations. The most commonly cited reason given for psychedelic drug use was "mind expansion," although a quarter of psychedelic drug users cited "spiritual" reasons for use. Present findings indicate that, although the 1960s have long passed and black market LSD unit doses have dramatically declined, illicit use of psychedelic drugs LSD and psilocybin is still significantly associated with experiences that can be characterized as mystical, transcendental or spiritual in nature, a relationship which appears to be dose-dependent. Self-reported doses of the quasi-psychedelic drug MDMA, on the other hand, did not predict such experiences in this sample, nor did any other drug examined.

Although LSD and psilocybin have long been recognized as capable of inducing mystical experiences, Horgan (2003) suggested that, as yet, no "psychedelic saints" have emerged from the psychedelic user subculture. Horgan's comment begs the question of how to determine "saint-hood" outside of an established religious tradition such as Catholicism. Lerner and Lyvers (2006) found that users of psychedelics such as LSD or psilocybin differed from users of nonpsychedelic drugs such as cannabis in terms of higher empathy scores and higher scores on LVI creativity, spirituality, concern for others and concern for the environment in the former group. The authors speculated that such differences may in part have resulted from psychedelic mystical experiences in the former group. However, in the present study the strong positive relationships between self-reported dose of LSD or psilocybin and scores on the two mystical experience questionnaires, coupled with the lack of relationships between psychedelic drug dose and scores on empathy, spirituality, concern for others and concern for the environment, suggest a different interpretation. For various reasons those who choose to use psychedelic drugs may on average place greater value on empathy, concern for the environment, creativity, and spirituality than those who do not choose to use psychedelics, as previously found by Lerner and Lyvers in both Israel and Australia, but the present results do not suggest that those differences specifically arise out of psychedelic-induced mystical experiences. Rather the group differences found by Lerner and Lyvers likely reflect the self-selected nature of psychedelic users and their associated subculture, which even today may share many of the values of the "hippie" movement of the 1960s. In mystical religious traditions perhaps the posited relationship between nondrug-induced spiritual enlightenment and "saintly" values - exemplified by the Mahayana Buddhist ideal of the enlightened Bodhisattva as one dedicated to reducing the suffering of all sentient beings - may to a significant extent reflect the nature of the person who undertakes such a rigorous mystical quest through traditional means, typically requiring many years of highly demanding sacrifices and self-discipline in search of ultimate truth, rather than the transient mystical experience of enlightenment per se (Harris 2011).

The present findings that higher self-reported doses of the psychedelic drugs LSD and psilocybin were associated with higher scores on two indices of mystical experiences should not be interpreted as encouraging psychedelic drug use, much less use of high doses. Although both LSD and psilocybin are physically very safe, the psychological hazards of uncontrolled use can be quite high, as was demonstrated in the 1960s when uncontrolled LSD use was widespread (e.g., Cohen 1970). Panic reactions and "bad trips" followed by post-traumatic stress symptoms such as "flashbacks" were widely reported among casual users of psychedelic drugs in the 1960s, although such reactions tend to be much rarer when the drugs are taken by psychologically stable, mature participants in a supportive, controlled environment (as in the recent study by Griffiths *et al*. 2006). Nevertheless even in the latter experiment about one third of participants reported "significant fear" (p. 15) during their psilocybin experience. Griffiths and colleagues noted that under uncontrolled conditions such reactions might easily lead to irrational behavior that could be dangerous to the user or to others. Given the unpredictability and intensity of psychedelic drug effects, such drugs should never be taken casually. Any future licit applications of such drugs are likely to be restricted to highly controlled circumstances involving careful screening, preparation and support of those who take these substances for a specific purpose, whether medical or spiritual.

Abstract

Psilocybin can occasion mystical-type experiences with participant-attributed increases in well-being. However, little research has examined enduring changes in traits. This study administered psilocybin to participants who undertook a program of meditation/spiritual practices. Healthy participants were randomized to three groups (25 each): (1) very low-dose (1 mg/70 kg on sessions 1 and 2) with moderate-level ("standard") support for spiritual-practice (LD-SS); (2) high-dose (20 and 30 mg/70 kg on sessions 1 and 2, respectively) with standard support (HD-SS); and (3) high-dose (20 and 30 mg/70kg on sessions 1 and 2, respectively) with high support for spiritual practice (HD-HS). Psilocybin was administered double-blind and instructions to participants/ staff minimized expectancy confounds. Psilocybin was administered 1 and 2 months after spiritual-practice initiation. Outcomes at 6 months included rates of spiritual practice and persisting effects of psilocybin. Compared with low-dose, high-dose psilocybin produced greater acute and persisting effects. At 6 months, compared with LD-SS, both high-dose groups showed large significant positive changes on longitudinal measures of interpersonal closeness, gratitude, life meaning/purpose, forgiveness, death transcendence, daily spiritual experiences, religious faith and coping, and community observer ratings. Determinants of enduring effects were psilocybin-occasioned mystical-type experience and rates of meditation/spiritual practices. Psilocybin can occasion enduring trait-level increases in prosocial attitudes/behaviors and in healthy psychological functioning.

Introduction

Quantum change experiences refer to sudden, distinctive, benevolent, and often profoundly meaningful experiences that are said to result in personal transformations that affect a broad range of personal emotions, cognitions and behaviors (Miller, 2004; Miller and C'de Baca, 2001). The phenomenon of quantum change is differentiated from the usual process of behavioral change, which occurs in small incremental steps (James, 1902). Such experiences, which have been described in anecdotal reports dating back centuries, have been variously labeled as mystical experiences, conversion experiences, religious experiences, peak experiences, transcendental experiences, transforming moments, or epiphanies (e.g. James, 1902; Maslow, 1968; Miller and C'de Baca, 2001; Stace, 1960). Although numerous cases of such quantum change experiences have been described, they have generally not been examined in prospective experimental studies because such experiences occur at low rates and usually unpredictably (Paloutzian and Park, 2013).

Administration of psilocybin, a classic psychedelic, provides a model for experimental investigation of quantum change experiences. Controlled, double-blind clinical trials in healthy volunteers show that under supportive conditions psilocybin can reliably occasion deeply personally meaningful and often spiritually significant experiences (e.g. mystical-type experiences) (Griffiths *et al*., 2006, 2011; Pahnke, 1963) having many characteristics similar to those described for quantum change experiences (Miller and C'de Baca, 2001). Such psilocybin effects are dose dependent (Griffiths *et al*., 2011) and have been demonstrated under conditions that provide substantial controls for expectancy bias (Griffiths *et al*., 2006, 2016). Although participants often attribute enduring positive changes in well-being and worldview to such experiences, there is little evidence from studies in healthy volunteers that psilocybin produces enduring changes on well-validated trait measures of disposition or personality (Darling *et al*., 2004; Doblin, 1991; Griffiths *et al*., 2008; 2011; Leary *et al*., 1963; Pahnke, 1963; Studerus *et al*., 2011). For example, a previous study in 36 participants who received a high dose of psilocybin showed enduring positive changes in moods, attitudes, and behavior attributed to the psilocybin experience, but no significant changes from screening to 14-month follow-up on various measures of personality, quality of life, faith maturity, and spiritual well-being (Griffiths *et al*., 2008). A later post-hoc analysis which combined data from that study with data from a similar subsequent study with 18 participants (Griffiths *et al*., 2011) showed that psilocybin-occasioned mystical-type experiences were associated with increases in the personality trait of openness (MacLean *et al*., 2011).

Although an older literature on psilocybin-assisted psychotherapy in psychiatric patient populations suggests that administration of psilocybin in a psychotherapeutic context may produce enduring decreases in psychopathology and increases in positive worldview and dispositional characteristics, methodological limitations render those reports inconclusive (Passie, 2004, 2007). However, recent placebo-controlled trials in psychologically distressed cancer patients showed that psilocybin produced decreases in anxiety and depression and increases in quality of life that persisted for at least a month and possibly 6 months or more (Griffiths *et al*., 2016; Grob *et al*., 2011; Ross *et al*., 2016).

The present study in healthy participants sought to extend understanding of possible enduring effects of quantum change experiences generally and psilocybin-occasioned experiences specifically by manipulating psilocybin dose and the intensity with which participants were encouraged to engage in meditation and other spiritual practices. Acute psilocybin effects, retrospective attributions to the experience, and enduring changes in prosocial attitudes and behaviors, and psychological functioning were assessed. More specifically, the present study used an across-group design to compare these outcomes in three groups of 25 healthy participants: (1) low-dose (active placebo) psilocybin with moderate-level ("standard") support for spiritual practice; (2) high-dose psilocybin with standard support; and (3) high-dose psilocybin with high support.

Materials and methods

Participants

Participants were recruited from the local community through flyers seeking volunteers interested in developing their spiritual lives by participating in a study of the combined effects of meditation and psilocybin, a psychoactive substance found in mushrooms used as sacraments in some cultures. In total, 1305 individuals were screened by telephone and 184 were further screened in person. Primary reasons for exclusion between phone screen and inperson screening were prior use of psychedelics (312); medical/ psychiatric exclusion (288); pre-existing regular meditation or other spiritual practice (261); logistics or lack of interest (220). Eighty-five volunteers were enrolled in the study and 10 did not complete the study. Reasons for non-completion included illness or a disqualifying medical or psychological issue (five volunteers), noncompliance with study procedures for personal or job-related reasons (three volunteers), and missing data on key measures (two volunteers). The 75 study completers (40% male) were medically healthy (as determined by medical history, physical examination, an electrocardiogram, routine medical blood laboratory tests, and urine testing for common drugs of abuse), and psychiatrically healthy. They were without personal or family histories of psychotic disorders or bipolar I or II disorder as determined by structured clinical interviews. Individuals with current alcohol or other drug dependence (including nicotine) were excluded, as were individuals with a past history within the past 5 years of alcohol or drug dependence (excluding nicotine). Twenty-five percent of participants reported past use of a psychedelic, with a mean of 25.1 years since last use. Participants were excluded if they reported any history of either spontaneous or psychedelic-occasioned salient mystical-type experiences. Participants had a mean age of 42 years (range 22 to 69) and a mean weight of 71.5 kg (range 49.2 to 97.5); 89% had college or post-graduate degrees and 87% were full-time employees or students. Although 31% reported practicing seated meditation, the mean frequency of practice was very low (1.1 times per month for the group). Volunteers did not receive monetary compensation for participation. Based on interviews, their motivation for participation was their interest in learning meditation, exploring their spiritual lives, and their curiosity about the effects of psilocybin. The Johns Hopkins IRB approved the study. Written informed consent was obtained from participants.

Study design and overview

The study procedures followed recommendations provided for safe conduct of research administering high doses of a classic psychedelic (Johnson *et al*., 2008). This study investigated the effects of psilocybin dose and the frequency and intensity of support provided for spiritual practice (i.e. meditation, spiritual awareness practice, journaling) on a battery of attitudinal and behavioral outcome measures in 75 healthy participants. The psilocybin dose manipulation was double-blind.

The duration of each volunteer's participation was approximately 6 to 8 months. After enrollment and before the first of two psilocybin sessions (described below), each participant had several preparation meetings with two study staff trained to serve as session "guides." The two psilocybin sessions were separated by about 1 month. Some measures were assessed during and immediately after sessions, and various longitudinal measures were evaluated immediately after study enrollment (i.e. baseline assessment) and 4 months after the second psilocybin session (i.e. 6-month assessment).

Assignment to the three experimental groups

After screening and study enrollment, each participant was randomized to one of three groups of 25 each: (1) very low-dose psilocybin (1 mg/70 kg on sessions 1 and 2 - functionally a placebo) with standard support for spiritual practice (LD-SS); (2) high-dose psilocybin (20 and 30 mg/70 kg on sessions 1 and 2, respectively) with standard support for spiritual practice (HD-SS); and (3) high-dose psilocybin (20 and 30 mg/70 kg on sessions 1 and 2, respectively) with high support for spiritual practice (HD-HS). An urn randomization procedure (Stout *et al*., 1994) was used to balance the three groups as closely as possible on six dichotomous variables (gender, age at study intake, lifetime psychedelic use, baseline lifetime Hood Mysticism Scale score, baseline frequency of meditation, and staff judgment about whether the participant was especially likely to engage in spiritual practices). Table 1 shows that these and other demographic characteristics did not differ across the three experimental groups.

Table 1. Participant demographics.

Measure	Low-Dose Standard-Support (N=25)	High-Dose Standard-Support (N=25)	High-Dose High-Support (N=25)	Group Comparisons
Gender (Male/Female)	9/16	13/12	8/17	N.S.
Age in years (mean, SEM)	40.2 (2.5)	41.0 (2.7)	45.6 (2.3)	N.S.
Weight in kilograms (mean, SEM)	69.0 (2.2)	72.6 (2.4)	72.9 (2.6)	N.S.
Race/Ethnicity				
White	76%	88%	92%	N.S.
Black/African American	8%	4%	4%	
Asian	16%	8%	4%	
Hispanic	4%	8%	4%	
Education (college or post-graduate degree)	96%	84%	88%	N.S.
Employment				
Full-time job or student	84%	84%	92%	N.S.
Part-time, retired or unemployed	16%	16%	8%	
Life-time Use of Psychedelics				
Percent reporting any past use[1]	32%	28%	20%	N.S.
Current Meditation				
Percent reporting some meditation	24%	36%	32%	N.S.
Times per month for the group (mean, SEM)	1.08 (0.44)	1.36 (0.46)	1.00 (0.37)	N.S.
Mysticism Scale Score (mean, SEM)	175.0 (8.1)	166.3 (13.8)	190.3 (10.0)	N.S.
Judged very likely to do spiritual practices[2]	8%	8%	8%	N.S.

N.S. = No significant differences between groups; ANOVA was used for continuous variables; Chi-square was used for categorical variables, with White compared to other racial categories combined and Full-time job or student compared to other employment categories combined.

[1] Mean number of years since last use among those who reported using was 25.1 years.

[2] Judgment made by based on an interview by one of the investigators.

Instructions to participants and guides, and the purpose of a third session

Study instructions and procedures were designed to minimize some of the effects of expectancy. Participants and guides were told that participants would receive psilocybin during each session, that dose levels could range between very low to high, that each participant would receive two or more different dose levels across two or three sessions, and that all participants would have at least one session with a moderately high or high dose of psilocybin. Although the most important comparative data on attitudinal and behavioral change were obtained in the first two sessions and subsequent follow-up, 39 participants were assigned to receive a third session after the 6-month data assessment in which they received 30 mg/70 kg psilocybin. This design feature was used in part to control expectancies through the 6-month follow-up evaluation. Although participants and guides were informed that over two or three sessions all participants would receive one or more high doses of psilocybin, they were not informed which participants or how many participants would be scheduled for a third session, nor were they told that the third session would be a high dose. In fact, all 25 participants in the low-dose psilocybin group (LD-SS) were assigned to receive a third session. An additional 14 participants (eight and six from HD-SS and HD-HS, respectively) were also assigned to receive a third session. Nine of these 14 participants were distributed within the first one-third (25) participants enrolled in the study. The purpose of scheduling a third session in these 14 participants was to obscure the study design from the guides early in the trial and reduce the possibility that guides would have strong expectancies whether or not a participant would have a third session. Data from the third session and data from several exploratory measures are beyond the scope of this report and are not presented.

Guide-participant meetings and support for spiritual practice

The guide-participant meetings served the functions of establishing rapport, providing specific preparation for the psilocybin sessions (see Johnson *et al*., 2008), and providing instructions and support for spiritual practices. The primary guides had established personal meditation practices as well as extensive experience supporting psilocybin sessions. An assistant guide was usually present at these meetings. Except for the dialogue-group meetings described below, the same primary and assistant guides were paired with a given participant throughout the study. Guide-participant meetings began and ended with a brief period of meditation.

Standard-Support groups

The frequency of guide-participant meetings differed across the standard vs. high-support conditions. Before the first psilocybin session (in the 1-month period following enrollment) guides and participants in the two standard-support groups (Low-Dose Standard-Support group; High-Dose Standard-Support group) had three 1-hour meetings and one 2-hour meeting (5 total contact hours). After each of the first two psilocybin sessions, participants in the standard-support group met for 1 hour within one or two days (usually one day) and had a 10 minute teleconference with guides about 2 weeks later. Thus, the total guide-participant contact hours for those in the Standard-Support groups from study acceptance to the 6-month follow-up was about 7 hours and 20 minutes.

High-Support group

Before the first session (in the 1 month period following enrollment) participants and guides in the High-Dose High-Support group had five 2-hour meetings (10 total contact hours). Between the first and second psilocybin sessions (1 month apart) there were three 1-hour participant-guide meetings (3 total contact hours). As with the Standard-Support groups, the first of these meetings was scheduled within a day or two following the session. During the 4-month period after the second psilocybin session, 1-hour participant-guide meetings occurred within a day or two of the session, at weekly intervals for the first 2 weeks, and at twice-monthly intervals for the remainder of the 4 months (10 contact hours). Also during the 4-month period after the second psilocybin session, participants in the High-Support group participated in twice-monthly 90-minute dialogue-group sessions. Approximately eight study participants plus one or two facilitators (study staff) participated in each session. The group membership changed over sessions as individual participants entered and left the group as they progressed through the study. The facilitators provided an opportunity to discuss psilocybin experiences but mainly encouraged dialogue about successes and challenges in implementing and sustaining the regular spiritual practices of meditation, spiritual awareness, and journaling. The total guide-participant contact hours for the High-Support group from study acceptance to the 6-month follow-up was 35 hours.

Spiritual practice support

At the first guide-participant meeting, each participant was given: (1) a copy of the book, *Meditation: A Simple 8-Point Program for Translating Spiritual Ideals into Daily Life* (Easwaran, 1991/1978); (2) a blank journal; and (3) a one-page outline of spiritual practice suggestions. All participants were required to read the book on meditation and integration of spiritual values into daily life. This book was used as a primary teaching resource because its approach provides an easily understood, nonsectarian program for spiritual living that has shown increases in measures of spirituality, well-being, self-efficacy, and health outcomes (Flinders *et al.*, 2007; Oman *et al.*, 2006, 2008a,b). The spiritual practice suggestions had three primary elements: meditation (10 to 30 minutes of sitting meditation daily); daily awareness practice (use of mantra and one-pointed attention in daily activities); and daily self-reflective journaling of insights, benefits, and challenges of spiritual practice in daily life. Participants were also encouraged to engage in activities they personally judged to facilitate spiritual growth (e.g. being in nature, contemplative movement, artwork, or service activities). At each of the guide-participant meetings, the guide asked about, encouraged, and offered instructions in the participant's implementation of the spiritual practice suggestions.

Psilocybin sessions

Psilocybin doses were prepared in opaque, size 0 gelatin capsules of identical appearance, with lactose as the inactive capsule filler. On each session, a single capsule was administered with 180 mL water. As described in more detail previously (Griffiths *et al.*, 2006), psilocybin sessions were conducted in an aesthetic livingroom-like environment with two guides present. Participants were instructed to consume a low-fat breakfast before arriving at the research unit at about 08:15 in the morning. A urine sample was taken to verify abstinence from common drugs of abuse and that female participants were not pregnant. For most of the time during the session, participants were encouraged to lie down on the couch, use an eye mask to block external visual distractions, and use headphones through which a program of classical and world music was played. The same music program was played for all participants in all sessions. Throughout the session, guides were nondirective and supportive and they encouraged participants to focus their attention on their inner experiences.

Measures assessed throughout the session

Ten minutes before and 30, 60, 90, 120, 180, 240, 300, and 360 minutes after capsule administration, blood pressure, heart rate, and monitor ratings were obtained by session guides as described previously (Griffiths *et al.*, 2006). Blood pressure (systolic and diastolic pressure using oscillometric method with the blood-pressure cuff placed on the arm) and heart rate were monitored using a Non-Invasive Patient Monitor Model 507E (Criticare Systems, Inc., Waukesha, WI). At the same time-points the two session guides completed the Monitor Rating Questionnaire, which involved rating or scoring several dimensions of the participant's behavior or mood (Table 2). The dimensions that are expressed as peak scores in Table 2 were rated on a 5-point scale from 0 to 4. Data were the mean of the two monitor ratings at each time-point.

Measures assessed 7 hours after drug administration

When psilocybin effects had subsided, participants completed four questionnaires: *Hallucinogen Rating Scale (HRS)* (Strassman *et al.*, 1994); *5-Dimension Altered States of Consciousness (5DASC)* (Dittrich, 1998); *Mysticism Scale* (Experience-specific version rated on a 9-point scale) (Hood *et al.*, 2001, 2009); and the *States of Consciousness Questionnaire (SOCQ)* (Griffiths *et al.*, 2006). Thirty items on the SOCQ comprise the *Mystical Experience Questionnaire* (MEQ30), which has been shown to be sensitive to mystical-type subjective effects of psilocybin in laboratory studies as well as in survey studies of psilocybin mushroom use (Barrett *et al.*, 2015; MacLean *et al.*, 2012). A total score (mean of all 30 items) and four factor scores were assessed: (1) Mystical, comprising items assessing internal and external unity, sacredness, and noetic feelings; (2) Positive mood (e.g. joy, peace awe); (3) Transcendence of time and space; (4) Ineffability. A participant was designated as having had a "complete" mystical experience if scores on each of the four factors was ≥60% of the maximum possible factor score (Barrett *et al.*, 2015). The MEQ30 is a psychometrically more rigorous derivation of the Pahnke-Richards scale, which has been described previously (Griffiths *et al.*, 2006).

Table 2. Cardiovascular measures and guide ratings of volunteer behavior and mood assessed throughout the session.

Measure	Low-Dose Standard-Support	High-Dose Standard-Support	High-Dose High-Support
Cardiovascular Measures (peak effects)			
Systolic blood pressure (mm Hg)	129.38 (2.37)	145.50 (2.62)***	148.54 (3.33)***
Diastolic blood pressure (mm Hg)	77.44 (1.71)	83.46 (1.68)**	85.22 (1.50)***
Heart rate (beats per minute)	75.74 (1.81)	91.04 (2.70)***	89.96 (2.77)***
Guide Ratings (peak effects, max score=4)			
Overall drug effect	1.17 (0.09)	2.68 (0.14)***	2.82 (0.10)***
Anxiety or Fearfulness	0.31 (0.09)	1.01 (0.17)*	1.43 (0.33)***
Distance from ordinary reality	0.75 (0.11)	2.46 (0.18)***	2.43 (0.11)***
Systematized ideas of reference	0.04 (0.02)	0.14 (0.05)	0.17 (0.06)*
Yawning	0.46 (0.15)	0.76 (0.23)	1.16 (0.24)*
Tearing/Crying	0.19 (0.11)	1.02 (0.17)	2.56 (0.72)***+
Nausea/vomiting	0.06 (0.04)	0.44 (0.15)*	0.5 (0.11)**
Joy/intense happiness	0.46 (0.09)	1.98 (0.20)***	1.8 (0.16)***
Peace/harmony	0.87 (0.13)	2.00 (0.20)***	1.72 (0.13)***
Psychological Discomfort	0.14 (0.06)	0.75 (0.17)**	0.87 (0.17)***
Physical Distress	0.07 (0.03)	0.56 (0.18)**	0.57 (0.13)**

Data are means of the peak response in each of the two psilocybin sessions in each participant. Group means with 1 SEM in parentheses (*n*=25) are shown.
Within a row, asterisks indicate a significant difference from the Low-Dose Standard-Support group (*p<.05, **p<.01, ***p<.001, Planned comparisons), and + indicates a significant difference between the High-Dose High-Support and High-Dose Standard-Support groups (p<.05, Planned comparisons).

Spiritual practices assessed at the 6-month follow-up

Spiritual practices questionnaire

This questionnaire assessed engagement with the three primary spiritual practices that were the focus of the spiritual practice teachings, the guide-participant meetings, and the dialogue-group meetings. Participants were instructed to complete the questionnaire based on their spiritual practices over the past 4 months (since the second psilocybin session). Participants rated the frequency and duration of their usual meditation practice, the frequency of their daily awareness practice (e.g. mantra repetition during daily activities), and the frequency of their self-reflective journaling.

Persisting effects assessed at the 6-month follow-up

Persisting effects questionnaire

This questionnaire assessed changes in attitudes, moods, behavior, and spiritual experience and has been shown sensitive to the effects of psilocybin 14 months after a psilocybin session (Griffiths *et al.*, 2011). Participants were asked to rate any current persisting effects that they attributed to the experiences during either or both of the two psilocybin sessions. One hundred forty items were rated on a 6-point scale (0=none, not at all; 1=so slight cannot decide; 2=slight; 3=moderate; 4=strong; 5=extreme, more than ever before in your life and stronger than 4). Within the questionnaire, the items were labeled in six categories: Attitudes about life (13 positive and 13 negative items); Attitudes about self (11 positive and 11 negative items); Mood changes (9 positive and 9 negative items); Relationships (9 positive and 9 negative items); Behavioral changes

(1 positive and 1 negative item); Spirituality (22 positive and 21 negative items). The positive and negative items were intermixed within each category. For purposes of scoring the resulting 12 scales (positive and negative scales for each of six categories) scores were expressed as the percentage of the maximum possible score.

The questionnaire included three additional questions (see Griffiths *et al.*, 2006 for more specific wording): (1) How personally meaningful was the experience? (rated from 1 to 8, with 1=no more than routine, everyday experiences; 7=among the five most meaningful experiences of my life; and 8=the single most meaningful experience of my life); (2) Indicate the degree to which the experience was spiritually significant to you? (rated from 1 to 6, with 1=not at all; 5=among the five most spiritually significant experiences of my life; 6=the single most spiritually significant experience of my life); (3) Do you believe that the experience and your contemplation of that experience have led to change in your current sense of personal well-being or life satisfaction? (rated from +3=Increased very much; 0=No change; -3=Decreased very much).

Longitudinal measures assessed at baseline and at the 6-month follow-up

At baseline (immediately after study enrollment) and at the 6-month follow-up, a battery of measures focused on attitudes, dispositions, and behaviors thought to be relevant to changes that could occur with engagement in psilocybin-facilitated spiritual practice was assessed. These measures included the previously described *Hood Mysticism Scale (Lifetime)* completed with reference to lifetime experience (Hood *et al.*, 2001); *Faith Maturity Scale*, a questionnaire assessing the degree to which a person embodies the priorities, commitments, and perspectives of faith as these have been understood in mainline Protestant traditions (Benson *et al.*, 1993); *Brief RCOPE*, a measure of religious/spiritual coping with stressful life events (Pargament, 1999; Pargament *et al.*, 1998); *Daily Spiritual Experience Scale*, a measure of an individual's perception of and interaction with the transcendent in daily life (Underwood, 2006; Underwood and Teresi, 2002), scored from 5 (Many times a day) to 0 (Never/almost never); *Death Transcendence Scale*, a 26 item questionnaire rated on a 7-point scale that assesses five subscales reflecting attitudes about death (Hood and Morris, 1983; VandeCreek, 1999); *Gratitude Questionnaire (GQ-6)*, a measure of gratefulness and appreciation in daily life (McCullough *et al.*, 2002); *Coherence and Death Acceptance subscales of the Life Attitude Profile - Revised* (LAPR), these 15 questions assess a dimension (Coherence subscale) of life meaning reflecting a logically integrated analytical and intuitive understanding of self, others, and life in general and a dimension (Death Acceptance subscale) reflecting death acceptance (Reker, 2007); *Trait Forgiveness Scale*, a measure of trait forgiveness (Berry *et al.*, 2005); *TRIM-18*, a scale assessing forgiveness of interpersonal transgression (McCullough *et al.*, 2006); the 3-item *Forgiveness* subscale of the *BMMRS* (The Fetzer Institute, 1999); *Santification of Strivings* rated life strivings on the dimensions of sacred, spiritual, holy, heavenly, and blessed (Mahoney *et al.*, 2005); *Schwartz Value Scale*, a measure of relative importance of various life values (Schwartz, 1992, 1994); *Inclusion of Others in the Self* scale (IOS), a measure of interpersonal closeness (Aron *et al.*, 1992), mean score of ratings of closest person, closest family member, least close family member, a stranger, and a difficult personal relationship; *ASPIRES (Assessment of Spirituality and Religious Sentiments)*, a community observerrated and self-rated questionnaire assessing a construct that reflects an individual's effort to create a broad sense of personal meaning in his or her life, reflected in three factors: Prayer Fulfillment, Universality, and Connectedness (Piedmont, 2010); the *Dispositional Positive Emotions Scale*, a measure assessing seven scales of positive emotion (joy, contentment, pride, love, compassion, amusement, and awe) (Shiota *et al.*, 2006); *Life-Orientation Test-Revised (LOT-R)*, a measure of optimism associated with health outcomes (Scheier *et al.*, 1994); *Satisfaction with Life Scale* (Pavot and Diener, 1993); *Purpose in Life Test (PIL)*, a assessment of meaningfulness in life (Crumbaugh and Maholick, 1964); the *Nonattachment Scale* (NAS), a questionnaire designed to assess the Buddhist concept of nonattachment (Sahdra *et al.*, 2010); and the revised NEO Personality Inventory (NEO) (Costa and McCrae, 1992).

Community observer ratings of changes in participants' behavior and attitudes

This previously described measure was shown to be sensitive to enduring effects of psilocybin (Griffiths *et al.*, 2006, 2011, 2016). After acceptance into the study, each participant designated as raters three adults who were expected to have continuing contact with the participant (e.g. family members, friends, or colleagues at work). Ratings were conducted via a structured telephone interview approximately 1 week after the participant had been accepted into the study, 3 to 4 weeks after the last session, and as part of the 6-month follow-up. The interviewer provided no information to the rater about the participant. The structured interview consisted of asking the rater to rate the participant's behavior and attitudes using a 10 point scale (from 1=not at all, to 10=extremely) on 13 items: inner peace; patience; good-natured humor/playfulness; mental flexibility; optimism; anxiety; interpersonal perceptiveness and caring; negative expression of anger; compassion/social concern; expression of positive emotions (e.g. joy, love, appreciation); self-confidence; forgiveness of others; and forgiveness of self. For the first rating assessment, which occurred soon after acceptance into the study, raters were instructed to base their ratings on observations of and conversations with the participant over the past 3 months. On subsequent assessments, raters were told their previous ratings and were instructed to rate the participant based on interactions over the last several weeks. Data from each interview with each rater were calculated as a total score, with anxiety and anger scored negatively. Changes in each participant's behavior and attitudes after drug sessions were expressed as a mean change score (i.e. difference score) from the baseline rating across the raters. At the same assessment times, the community observer who knew the participant best (as judged by the participant at baseline) also completed via telephone interview the 35 item Observer Rated ASPIRES questionnaire, which assesses spirituality and religious sentiments (Piedmont, 2010). Seven of 225 (<6%) scheduled ratings by community observers at 6 months were missed due to failure to return calls or to the rater not having contact with the participant over the rating period.

Data analyses

Pearson Chi-square (SPSS version 22.0.0.0) was used to compare experimental groups on dichotomous variables (demographics and proportion of group endorsing specific responses). Planned comparisons among groups were conducted with z-tests of proportions.

For time-course data during psilocybin sessions, for each participant, peak score during the time-course was defined as the maximum value from pre-capsule to 6 hours post-capsule and time to peak effect was defined as the time to peak score. ANOVA (SAS version 9.2, PROC GLM) with planned comparisons between groups were used to analyze data at each time-point, peak effects, and time to peak effects for Sessions 1 and 2 separately. A similar analysis was conducted using mean peak data from Sessions 1 and 2 combined. Similar analyses were conducted comparing peak effects and time to peak effect between sessions 1 (20 mg/70 kg) and 2 (30 mg/70 kg) collapsing across the two high-dose groups (n=50).

A similar approach (ANOVA with planned comparisons between groups) was used to examine demographic data for continuous variables, data obtained 7 hours after psilocybin administration (end of session), and single time-point data from the 6-month follow-up (e.g. spiritual practices and persisting effects attributed to psilocybin).

Longitudinal measures (i.e. those measures assessed immediately after study enrollment and at the 6-month follow-up), were analyzed with a repeated measures regression model with AR(1) covariance structure (SAS version 9.2, PROC MIXED) with planned comparisons between groups. Measures that showed significant differences between groups at baseline were reanalyzed as difference from baseline scores using ANOVA (SAS version 9.2, PROC GLM) with planned comparisons between groups. If difference scores at 6 months were not significantly different between groups, those measures were dropped from further analysis. For the remaining longitudinal measures, planned comparisons between groups at 6 months were conducted. Finally, to determine if there were changes over time within each group, planned comparisons between baseline and 6-month data were examined.

Hierarchical regression analysis was used to explore the relationship of spiritual practices and psilocybin-occasioned mystical experience to various outcome measures. For this analysis, the three spiritual practice measures (minutes per day of mediation; times per day of spiritual awareness practice; times per week of spiritual journaling) were entered together in the first step of the regression model. In the second step, the mean of the Mystical Experience Questionnaire (MEQ30) total scores (completed after both psilocybin sessions) was entered into the regression model. In another analysis, MEQ30 mean total score was entered into the regression model first.

Results

Integrity of blinding procedures

After the psilocybin sessions had been completed, the five study staff members who had served as primary guides for the study completed a questionnaire that asked about their understanding of the study drug and dose conditions. Although all correctly believed that psilocybin had been administered, most made incorrect inferences about the drug or dose conditions, with three of five believing that doses higher than 30 mg/70 kg had been administered, two believing that four or more psilocybin dose levels had been administered; two believing that a drug other than psilocybin was administered (guesses included MDMA, ketamine, and dextromethorphan), and two believing that a true placebo had been administered. Surprisingly, some of these incorrect inferences were contrary to study design parameters that had been described verbally and in the consent form to participants and these primary study guides (e.g. administration of something other than psilocybin). None correctly understood the study design, although two correctly inferred that two lower dose sessions were followed by a high-dose third session.

Cardiovascular measures and guide ratings assessed throughout the session

Time-course

As expected, inspection of mean group data over time in the low-dose group (LD-LS) for sessions 1 and 2 showed evidence of only modest effects of 1 mg/70 kg psilocybin. In this group, cardiovascular effects generally reached peak at 30 minutes after capsule administration, while guide ratings reached peak at 120 minutes (Figure 1). Also as expected and as illustrated for guide ratings in Figure 1, the two high-dose groups showed similar time-courses and, compared with the low-dose group, effects in the two high-dose groups were larger, with peak cardiovascular effects occurring at 30 to 180 minutes and peak guide ratings occurring at 180 minutes. Analysis of differences in time to peak effects between the first and second sessions (20 vs. 30 mg/70 kg) for the two high-dose groups separately and combined did not show significant differences in time to peak effects for guide ratings. For the cardiovascular measures, only time to peak heart rate showed a significant difference, with peak effects occurring significantly earlier at the high dose (112 ± 13 vs. 163 ± 14 minutes for sessions 1 (20 mg/70 kg) and 2 (30 mg/70 kg) respectively, mean ± SEM for the two high-dose groups combined).

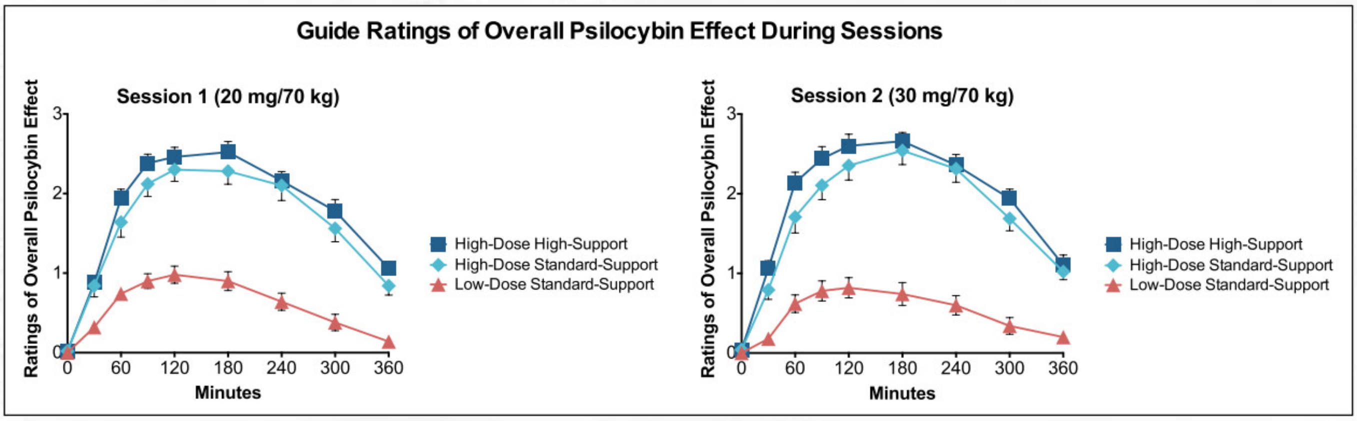

Figure 1. Within-session time-course of guide ratings of overall psilocybin effect during the sessions. Data points are means; brackets show ± 1 SEM (n=25); time 0=before capsule administration). The High-Dose High-Support and the High-Dose Standard-Support groups were significantly different from the Low-Dose Standard-Support group at all post-capsule time-points. The two high-dose groups were not significantly different at any time-points except for 60 and 90 minutes in Session 2.

Peak effects

Analysis of differences in peak effects for guide ratings between the first and second sessions (20 vs. 30 mg/70 kg) for the two high-dose groups separately and combined did not show significant differences. For the cardiovascular measures, peak systolic and diastolic pressures were modestly but significantly higher after the high dose (mean ± SEM for the two high-dose groups combined: 144 ± 2 vs. 150 ± 2 mm Hg systolic pressure for low and high doses, respectively, and 83 ± 1 vs. 86 ± 1 mm Hg diastolic pressure for low and high doses, respectively).

Given that differences between sessions 1 and 2 were minimal, and to simplify comparison across the three experimental groups, mean peak cardiovascular effects and guide ratings across the two sessions were used in subsequent analyses. For all three cardiovascular measures and for almost all of the guide ratings, the HD-SS and HD-HS groups were significantly higher than the LD-SS group (Table 2 and Figure 2). The HD-HS group differed from the HD-SS group only on guide ratings of tearing/ crying, which were higher in the HD-HS group.

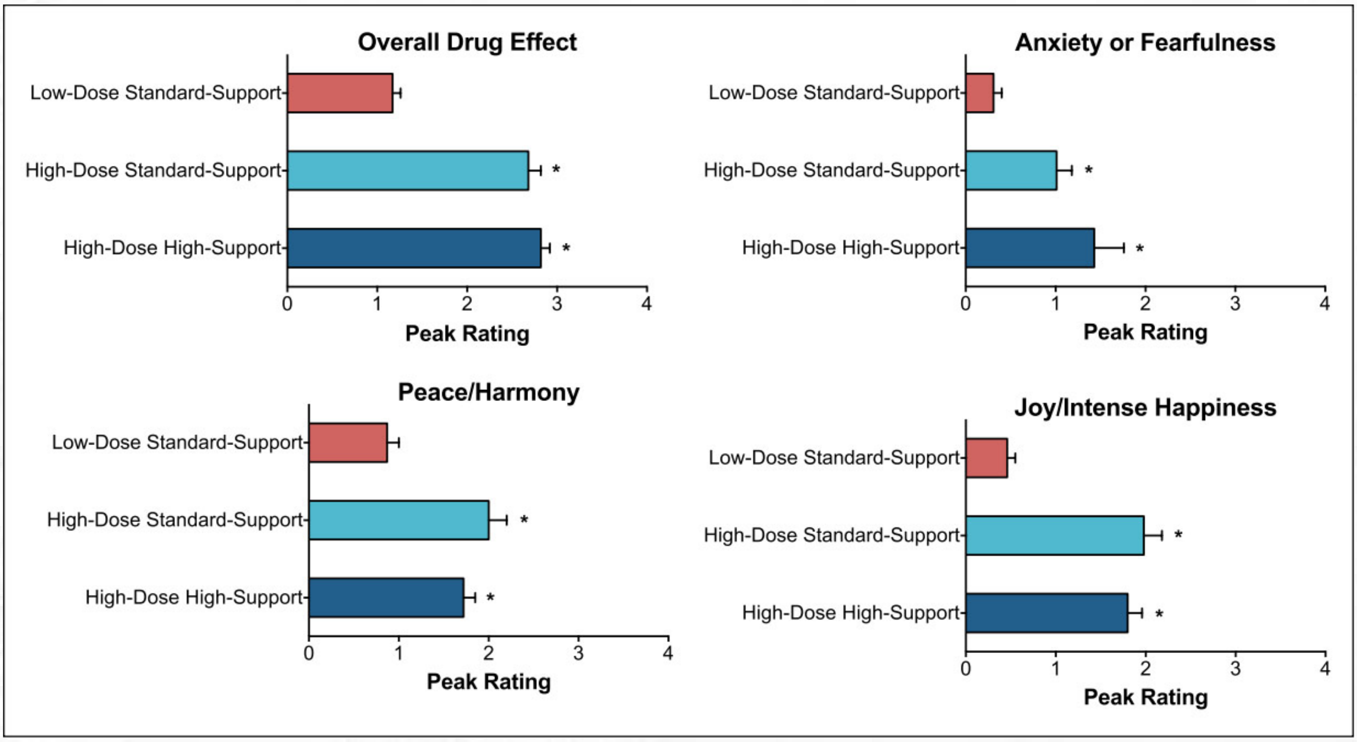

Figure 2. Guide ratings of volunteer behavior and mood assessed throughout the psilocybin sessions (Illustrative results from Table 2). Data are means of the peak response in each of the two psilocybin sessions in each participant. Bars show group means; brackets show 1 SEM; * indicates a significant difference from Low-Dose Standard-Support (Planned comparisons, p<.05); there were no significant differences between the High-Dose High-Support and High-Dose Standard-Support groups.

Drug effect and mystical-type effect measures assessed 7 hours after psilocybin administration

In an analysis similar to that described above for the peak scores during the session, participant-rated drug effect and mystical-type effect measures after psilocybin sessions did not show significant differences between sessions 1 and 2. Therefore, mean data across the two sessions were used in the analyses below.

Subjective effects questionnaires

Two participant-rated subjective effect questionnaires (HRS and 5D-ASC) completed at the end of the sessions showed a pattern of results across the experimental groups similar to peak effects from the cardiovascular and guide rated measures assessed throughout the session (Table 3). Specifically, the HD-HS and HD-SS groups were consistently higher than the LD-SS group, with no differences between the two high-dose groups. Results from these subjective measures, which were developed for sensitivity to hallucinogens, showed that psilocybin produced the expected range of subjective changes including changes in somatic effects, positive and negative affect, perception, cognition, and volition.

Table 3. Participant ratings on subjective effects and mystical experience questionnaires completed 7 hours after psilocybin administration.

Measure	Low-Dose Standard-Support	High-Dose Standard-Support	High-Dose High-Support
Hallucinogen Rating Scale (HRS)			
Intensity (max score=4.25)	1.33 (0.16)	2.92 (0.16)***	2.89 (0.11)***
Somesthesia (max score=4)	0.47 (0.07)	1.48 (0.14)***	1.53 (0.11)***
Affect (max score=4)	0.70 (0.08)	1.82 (0.14)***	1.98 (0.09)***

Transcendence of time and space (max score=100)	22.3 (4.1)	66.6 (5.6)***	70.6 (3.7)***
Ineffability (max score=100)	20.1 (4.1)	74.4 (6.3)***	76.3 (3.9)***
Total (max score=100)	19.4 (3.3)	65.9 (6.0)***	73.6 (3.1)***
Mysticism Scale			
Interpretation (max score=108)	48.82 (4.40)	82.42 (5.63)***	96.08 (2.39)***+
Introvertive (max score=108)	48.00 (3.74)	84.00 (5.13)***	93.20 (2.28)***
Extrovertive (max score=72)	27.44 (3.01)	48.62 (4.28)***	58.86 (2.37)***+
Total (max score=288)	124.26 (10.55)	215.04 (14.52)***	248.14 (6.14)***+

For each participant, ratings were collapsed across the two psilocybin sessions. Data are means with 1 SEM shown in parentheses (*n*=25); data for the 5D-ASC and MEQ30 are expressed as a percentage of the maximum possible score. Within a row, asterisks indicate a significant difference from the Low-Dose Standard-Support group (**p*<.05, ***p*<.01, ****p*<.001, Planned comparisons), and + indicates a significant difference between the High-Dose High-Support and High-Dose Standard-Support groups (*p*<.05, Planned comparisons).

Measures of mystical experience

Also at 7 hours after capsule administration, participants completed two questionnaires (MEQ30 and Mysticism Scale) designed to assess mystical experience (Table 3 and Figure 3). As with the other end-of-day ratings, the HD-HS and HD-SS groups were consistently higher than the LD-SS group. Furthermore, all the subscales from these questionnaires (which are believed to assess various aspects of mystical experience) are numerically higher in the HD-HS group than the HD-SS group and, for three of the four measures on the Mysticism Scale, these differences were significant (Table 3). The proportion of participants who met *a priori* criteria for having had a "complete" mystical experience on the MEQ30 on session 1 and 2, respectively, were 0% and 4% (LD-SS), 48% and 50% (HD-SS), and 44% and 52% (HD-HS). Overall, 4%, 61%, and 64% of participants in the LD-SS, HD-SS, and HD-HS groups had "complete" mystical experiences at either or both sessions 1 and 2.

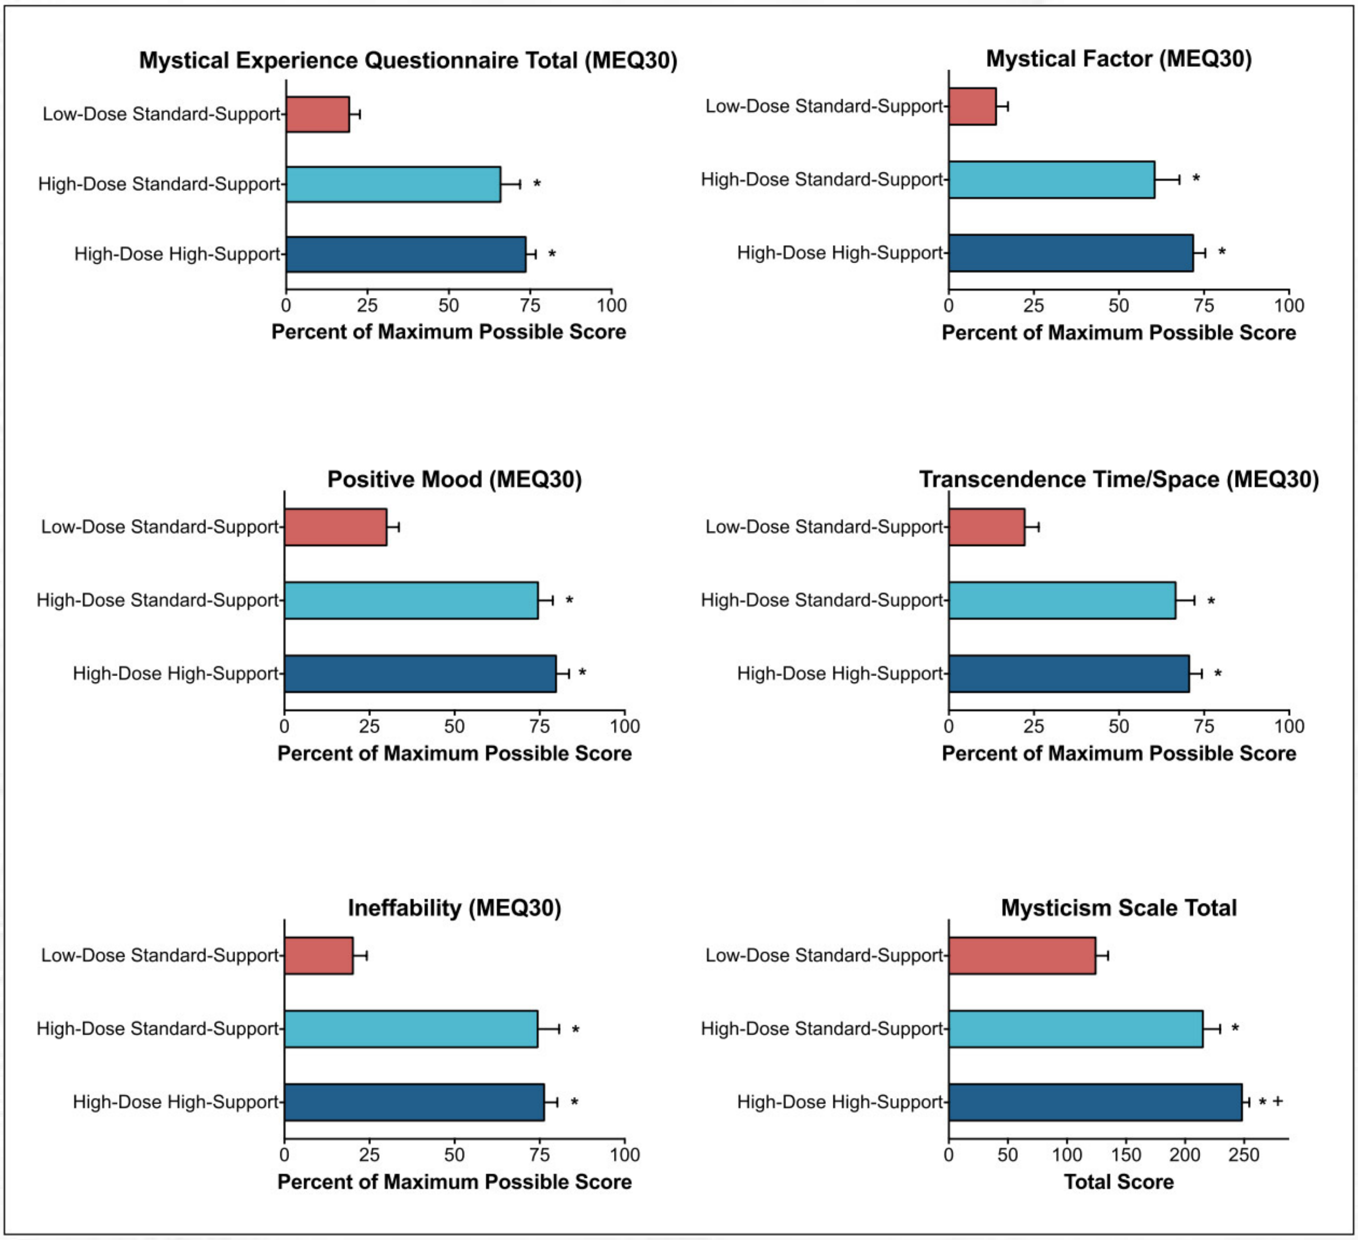

Figure 3. Participant ratings on mystical experience questionnaires completed 7 hours after psilocybin administration (Illustrative results from Table 3).
Data for the Mystical Experience Questionnaire (MEQ30) are percentages of the maximum possible score; data for the Mysticism Scale are total scores. Bars show group means; brackets show 1 SEM; * indicates a significant difference from the Low-Dose Standard-Support group; + indicates a significant difference between the High-Dose High-Support and the High-Dose Standard-Support groups (Planned comparisons, $p<0.05$).

Spiritual practices assessed at the 6-month follow-up

Spiritual practices questionnaire

Consistent with the more frequent and intensive support provided in the high spiritual support condition, rates of meditation, spiritual awareness practice, and journal writing in the HD-HS group were about twice the rates in the two standard-support groups, which were quite similar. Likewise, the percentage of participants meditating daily, engaging in spiritual practices daily, or journaling weekly was higher in the HD-HS group. As shown in Table 4 and Figure 4, the HD-HS group was significantly higher than the LD-SS and HD-SS groups on five and four, respectively, of these measures of engagement with spiritual practice. Moreover, the HD-HS group showed numerically larger effects for all six measures.

Table 4. Spiritual practices at 6 months.

Measure	Low-Dose Standard-Support	High-Dose Standard-Support	High-Dose High-Support
Meditation			
Minutes per day for all days	10.23 (2.24)	9.93 (1.69)	19.33 (0.20)**+++
Percentage of group meditating daily	32%	20%	64%*++
Spiritual awareness practice			
Times per day for all days	2.16 (0.74)	3.05 (0.87)	5.19 (0.97)*
Percentage of group practicing daily	56%	68%	96%**+
Journal writing			
Times per week	1.76 (0.49)	1.78 (0.50)	4.44 (0.52)***+++
Percentage of group journaling daily	12%	16%	40%

Data, which were obtained at the 6-month follow-up, show retrospective ratings for the past 4 months; rate data are means with 1 SEM shown in parentheses (*n*=25); proportion data are the percentage of group (*n*=25) reporting the spiritual practice.
Within a row, asterisks indicate a significant difference from the Low-Dose Standard-Support group (*p<.05, **p<.01, ***p<.001), and plus symbols indicate a significant difference between the High-Dose High-Support group and the High-Dose Standard-Support group (+p<.05, ++p<.01, +++p<.001). Significance levels were determined with z-tests for proportions for percentile data and with Planned comparisons for other numerical ratings.

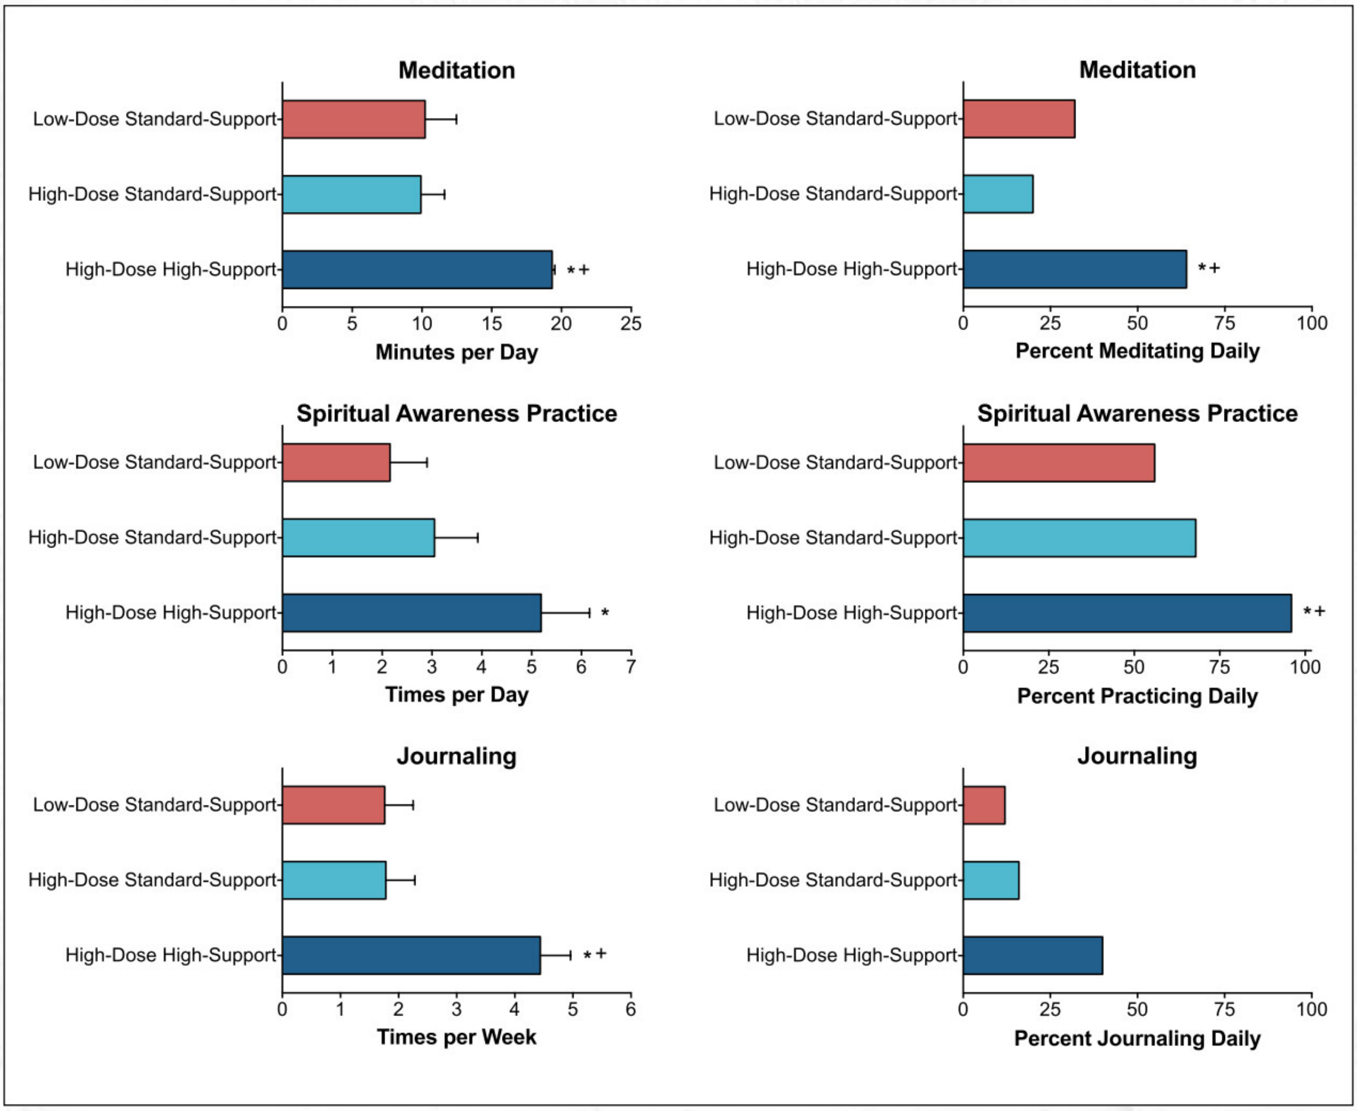

Figure 4. Spiritual practices at 6 months (from Table 4).
Data, which were obtained at the 6-month follow-up, show retrospective ratings for the past 4 months. Bars displaying rate data show means; brackets show 1 SEM (n=25). Meditation rate data are minutes per day for all days. Bars displaying proportion data show the percentage of the group (n=25) reporting the practice during the indicated time interval. * indicates a significant difference from the Low-Dose Standard-Support group; + indicates a significant difference between the High-Dose HighSupport group and the High-Dose Standard-Support group (Planned comparisons, p<0.05).

Persisting effects assessed at the 6-month follow-up

Table 5 and Figure 5 show participant ratings at the 6-month follow-up of effects that the participants attributed to either or both of the two psilocybin sessions. With regard to positive changes in attitudes, mood, altruism, and behavior as well as increased spirituality, the two high-dose groups were significantly higher than the LD-SS group on all these measures. Table S1 shows that the effect sizes for these comparisons were very large (mean Cohen's d=1.65). In addition, the HD-HS group was significantly higher than the HD-SS group on altruistic/positive social effects, positive behavior changes, and increased spirituality. Negative ratings of these same dimensions were very low and did not differ between groups except for negative attitudes about self that showed very small but significant increases in the HD-HS group. Of the eight participants in the HD-HS group that endorsed any increase in negative attitudes about self, all also rated the experience as having increased their sense of personal well-being or life satisfaction at the 6-month follow-up.

Table 5. Participant ratings of effects attributed to psilocybin session experiences at 6 month assessment.

Measure	Low-Dose Standard-Support	High-Dose Standard-Support	High-Dose High-Support
Attitudes, Moods, Behavior, & Spirituality			
Positive attitudes about life	22.71 (5.11)	61.66 (6.18)***	73.11 (4.14)***
Negative attitudes about life	0.98 (0.37)	1.66 (0.63)	3.02 (1.17)
Positive attitudes about self	23.85 (4.92)	55.35 (6.01)***	68.73 (4.22)***
Negative attitudes about self	0.44 (0.27)	2.04 (0.65)	4.00 (1.54)*
Positive mood changes	21.42 (4.42)	51.47 (5.96)***	65.42 (4.73)***
Negative mood changes	1.07 (0.60)	0.71 (0.28)	1.69 (1.30)
Altruistic/positive social effects	21.24 (4.44)	53.24 (5.85)***	67.02 (4.22)***+
Antisocial/negative social effects	0.8 (0.49)	0.36 (0.36)	1.16 (0.60)
Positive behavior changes	27.20 (4.98)	61.60 (6.76)***	78.40 (5.26)***+
Negative behavior changes	0.8 (0.82)	0.00 (0)	0.00 (0)
Increased spirituality	20.76 (4.95)	58.69 (6.36)***	73.62 (4.00)***+
Decreased spirituality	1.14 (0.44)	0.84 (0.36)	1.26 (0.94)
How personally meaningful was experience?			
Mean (max score=8)	3.80 (0.35)	6.76 (0.31)***	7.20 (0.14)***
% rating top 5 most personally meaningful	12%	84%***	84%***
% rating the single most personally meaningful	0%	28%*	36%**
How spiritually significant was the experience?			
Mean (max score=8)	2.60 (0.26)	4.68 (0.34)***	5.52 (0.12)***+
% rating top 5 most spiritually significant	12%	76%***	96%***+
% rating the single most spiritually significant	0%	40%**	56%***
Did the experience change your sense of of well-being or life satisfaction?			
Mean (max/min score= -3 to +3)	1.08 (0.23)	2.20 (0.23)***	2.60 (0.13)***
% rating moderately or very much (+2 or +3)	20%	72%***	92%***

Data on attitudes, mood, altruistic/social effects, behavior, and spirituality are means expressed as percentage of maximum possible score, with 1 SEM shown in parentheses (n=25); data for the final three questions are either mean raw scores with 1 SEM shown in parentheses or percentages of group (n=25).
Within a row, asterisks indicate a significant difference from the Low-Dose Standard-Support group (*p<.05, **p<.01, ***p<.001), and + indicates a significant difference between the High-Dose High-Support group and the High-Dose Standard-Support group (+p<.05). Significance levels were determined with z-tests for proportions for percentile data and with Planned comparisons for other numerical ratings.

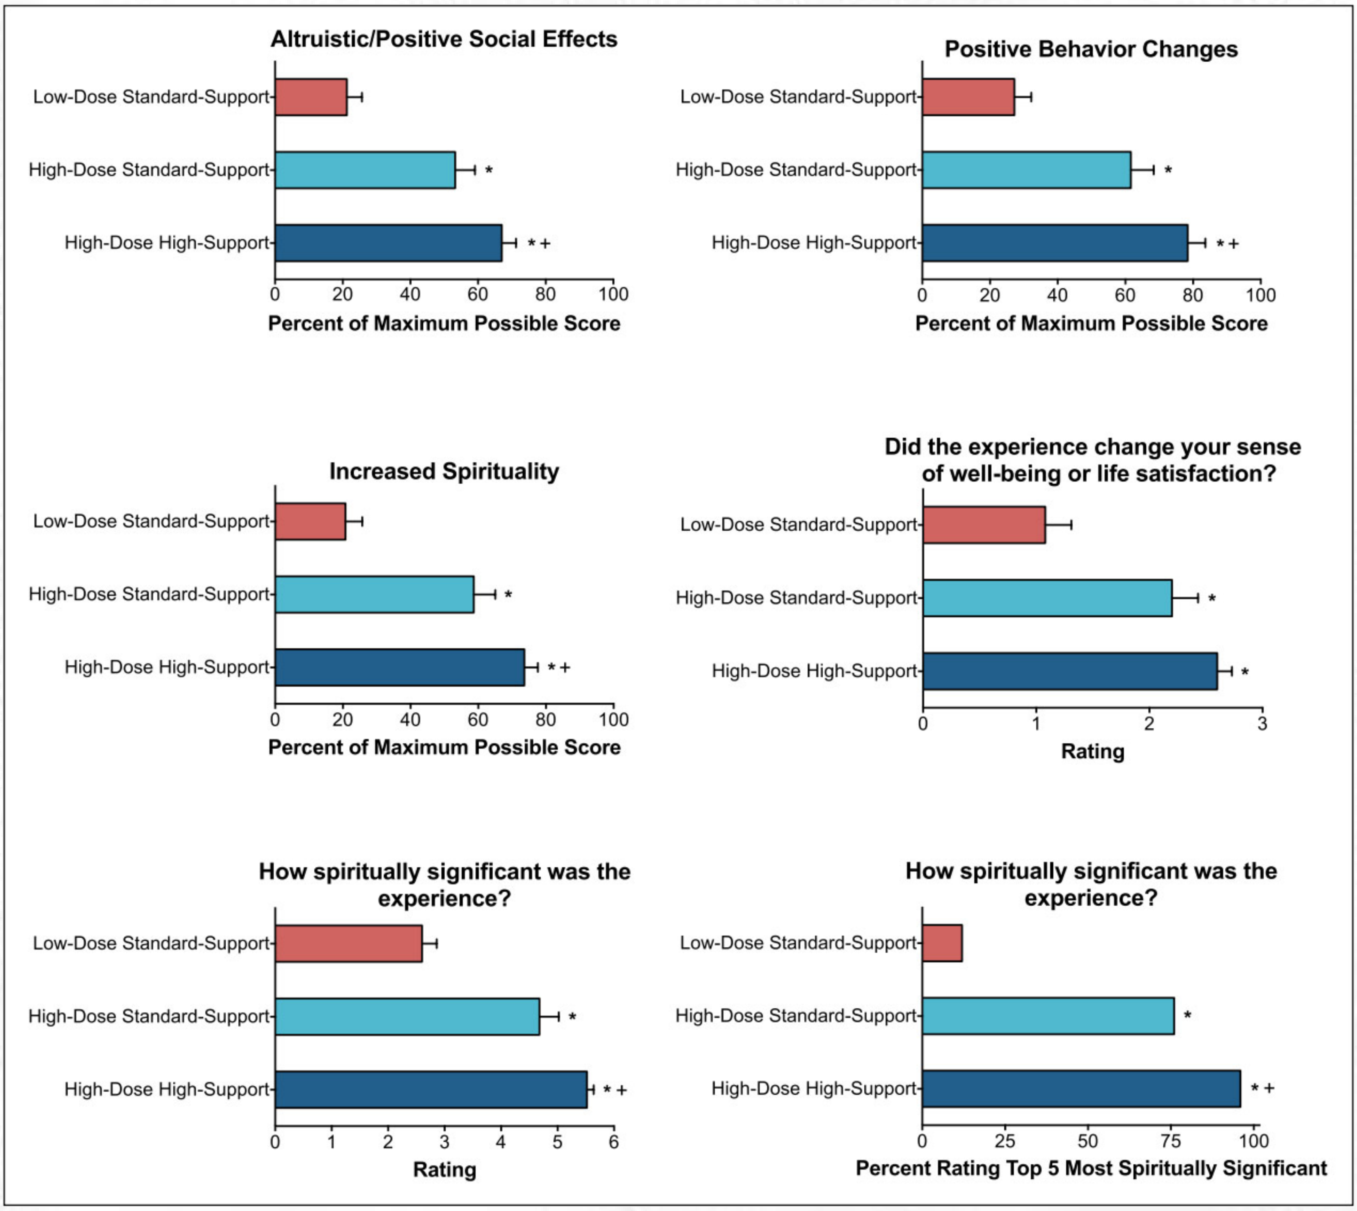

Figure 5. Participant ratings of effects attributed to psilocybin session experiences at the 6-month follow-up (Illustrative results from Table 5). Data on altruistic/social effects, behavior changes, and spirituality are expressed as percentage of maximum possible score (bars show means, brackets show 1 SEM, *n*=25). Data for the questions about spiritual significance and change in well-being or life satisfaction are either raw scores (bars show means, brackets show 1 SEM, *n*=25) or percentages of the group (*n*=25). * indicates a significant difference from the Low-Dose Standard-Support group; + indicates a significant difference between the High-Dose High-Support group and the High-Dose Standard-Support group (Planned comparisons, *p*<0.05).

Both the high-dose groups also rated the personal meaning, spiritual significance, and change in well-being or life satisfaction attributed to the sessions significantly higher than the LD-SS group (Table 5 and Figure 5). Similar findings were shown for the percentage of each group providing strong endorsements of these same three dimensions. For example, 12%, 76%, and 96% of the LD-SS, HD-SS, and HD-HS groups, respectively, rated the experience(s) among the top five most spiritual experiences of their lives, with 0%, 40%, and 56%, respectively, indicating it to be the single most spiritually significant experience of their life.

Longitudinal measures and community observer ratings assessed at 6 months

Analysis of longitudinal measures

Per the plan in the Data Analysis section, three longitudinal measures were dropped from analysis (Forgiveness subscale of the BMMRS; self-rated ASPIRES; and the Satisfaction with Life Scale) because of significant between-group differences at baseline and no significant difference in change from baseline. The

Purpose in Life Test, Nonattachment Scale, and the LOT-R [a measure of optimism] both showed significant increases from baseline to 6 months in the two High-Dose groups. The Openness scale of the NEO showed a significant increase from baseline to 6 months in the HD-HS group, but did not show a significant between-group difference at 6 months on Openness or the other four NEO scales. The DPES showed neither a significant increase from baseline to 6 months nor significant between-group differences at 6 months.

Table 6. Longitudinal measures assessed at 6 months that showed significant between group differences.

Measure	Low-Dose Standard-Support	High-Dose Standard-Support	High-Dose High-Support
Mysticism Scale: (Lifetime)			
Interpretation (max score=108)	75.64 (3.25)	**87.58 (5.10)***	**99.96 (2.05)***+**

Outcome measures are shown in the table if there was one or more significant difference between groups at 6 months; measures showing a between-group difference at baseline were excluded unless the between-group difference was also shown in the planned comparison of change from baseline score (6-month minus baseline score).
Data are means with 1 SEM shown in parentheses (_n_=25).
Within a row, asterisks indicate a significant difference from the Low-Dose Standard-Support group (*_p_<.05, **_p_<.01, ***_p_<.001, Planned comparison), and + indicates a significant difference between the High-Dose High-Support group and the High-Dose Standard-Support group (Planned comparisons, _p_<.05).
Within a row, boldface font indicates a significant difference within the group between baseline and 6 months (Planned comparisons, _p_>.05); for all such significant differences, 6-month scores were higher than baseline scores except for Avoidance Motivation in the TRIM-18 which were lower.
[1] Lower scores on this scale indicate more forgiveness.

Table 6 shows the 23 longitudinal measures that demonstrated significant between-group differences at 6 months (Table S2 shows corresponding effect sizes). In the LD-SS group, only one measure (a measure of forgiveness) was significantly different between baseline and 6 months (Table 6, boldface font). In contrast, in the two high dose groups, most of the 23 measures were significantly different between the baseline and 6-month assessment (boldface font). For all 23 measures, the HD-HS group showed numerically larger effects (in the expected direction) than the HD-SS group (Table 6 and Figure 6), with significant differences on seven measures. Furthermore, the HD-HS group differed significantly on all 23 measures from the LD-SS group and, in contrast, on 14 of 23 measures from the HD-SS group.

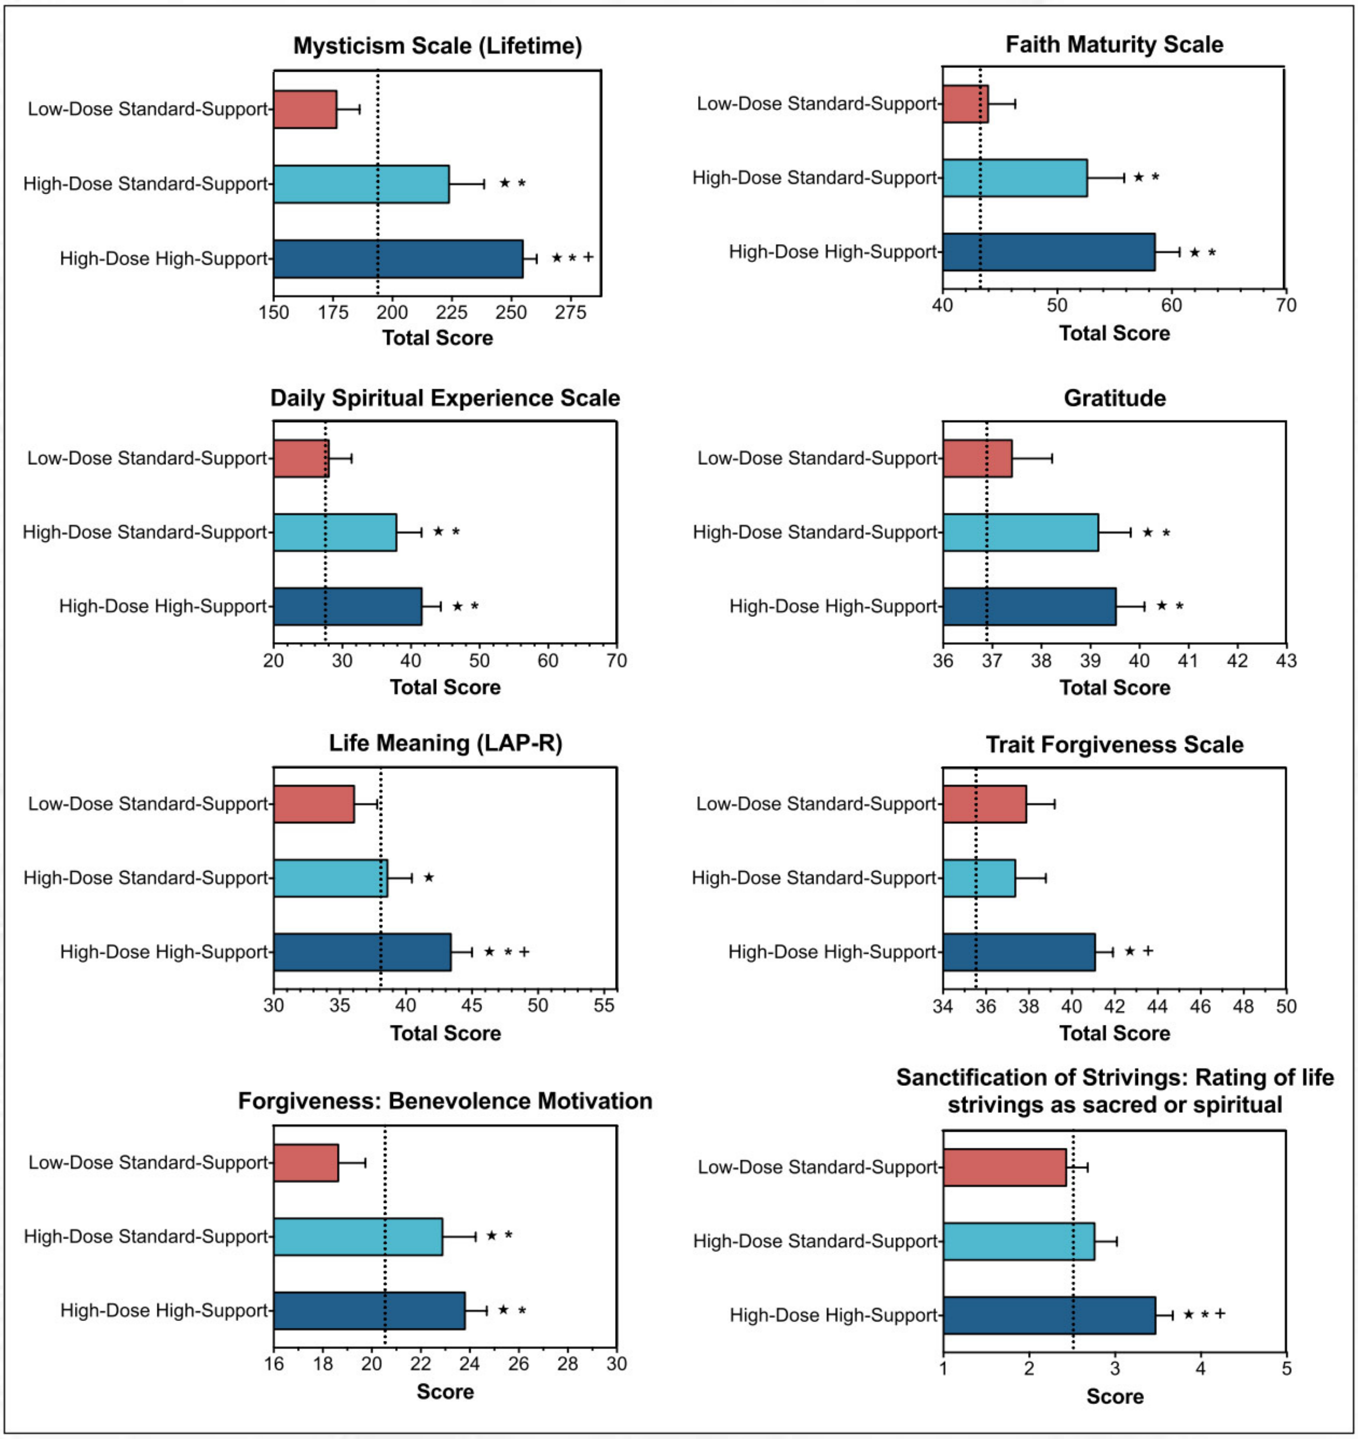

Figure 6. Longitudinal measures assessed at the 6-month follow-up (Illustrative results from Table 6). Bars show means; brackets show 1 SEM (*n*=25); &starf; indicates a significant difference between baseline and 6 months; * indicates a significant difference from the Low-Dose Standard-Support group; + indicates a significant difference between the High-Dose High-Support group and the High-Dose Standard-Support group (Planned comparisons, *p*<0.05). For comparison, dotted lines show mean scores from previous studies for each measure: Mysticism Scale (college students, Hood *et al*., 2001; Ralph W. Hood Jr, personal communication); Faith Maturity Scale (university students, Loma Linda University, 2007), Daily Spiritual Experience Scale (general population survey data, Underwood, 2006); Gratitude Questionnaire-6 (adults, McCullough *et al*., 2002); Life Meaning (college and community sample, Reker, 2007); Trait Forgiveness Scale (college students, Berry *et al*., 2005); Forgiveness Benevolence Motivation (college students, Tsang *et al*., 2006); Sanctification of Strivings (adults, Mahoney *et al*., 2005).

Community observer ratings

In addition to the various participant-rated longitudinal measures, it is noteworthy that several observer-rated measures (total score, prayer fulfillment, and universality on the ASPIRES and total change score on the community observer ratings of positive change in behavior and attitudes) generally showed the same pattern of differences across groups with the HD-HS group showing the largest effects (Table 6 and Figure 7).

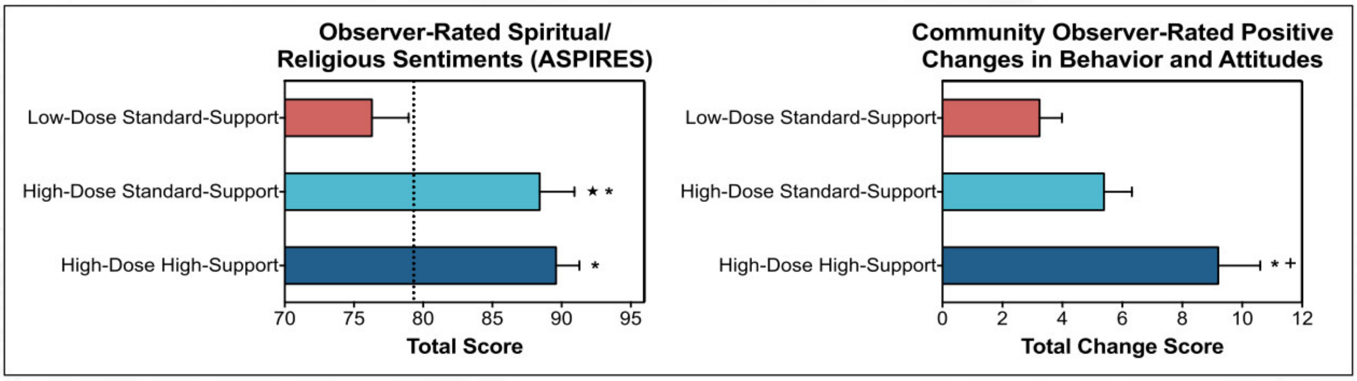

Figure 7. Two observer-rated measures of participant attitudes and behavior assessed at the 6-month follow-up (from Table 6). Bars show means; brackets show 1 SEM (*n*=25); for both measures, * indicates a significant difference from the Low-Dose Standard-Support group; + indicates a significant difference between the High-Dose High-Support group and the High-Dose Standard-Support group (Planned comparisons, *p*<0.05). For the ASPIRES, which was assessed both at baseline and the 6-month follow-up, &starf; indicates a significant difference between baseline and 6 months (Planned comparisons, *p*<0.05). Also for the ASPIRES, dotted line shows mean norm score (Piedmont, 2010).

Relationship of spiritual practice and psilocybin-occasioned mystical experience to various outcome measures

Hierarchical regression analysis was used to determine the relationship of spiritual practice and psilocybin-occasioned mystical experience to various outcome measures from Tables 5 and 6 that showed between-group differences at 6 months. For this analysis, the three spiritual practice measures (minutes per day of mediation; times per day of spiritual awareness practice; times per week of spiritual journaling) were entered together in the first step of the regression model. Mean total score from the Mystical Experience Questionnaire (MEQ30) was entered into the regression model in the second step. As shown in Table 7, spiritual practices accounted for a significant proportion of variance (R^2) in 13 of 19 outcome measures, with R^2 ranging from .050 to .293 (mean=.139). As also shown in the table, mystical experience score (MEQ30) accounted for a significant proportion of variance in 18 of 19 measures after accounting for the impact of spiritual practices, with the change in R^2 ranging from .031 to .619, (mean=.266). In contrast to MEQ30 score which was significant for 18 measures even after accounting for the contribution of spiritual practices, the rightmost columns of the table show that, for the overall regression model, meditation, awareness practice, and journaling were significant for six, two and one of the outcome measures, respectively. Not shown in the table, when MEQ30 score was entered as the first step of a regression model, it accounted for a significant proportion of variance in all 19 outcome measures, with R^2 ranging from .123 to .747 (mean=.351).

Table 7. Hierarchical regression analysis of the relationship of spiritual practices and mystical experience to the outcome measures.

Outcome Measure	Spiritual Practices* entered first					Change in model adding post-session mystical experience score (MEQ30)					Beta (standardized coefficient)				t				*p*

The first 15 measures are total scores from measures shown in Table 6 and the last four measures are from Table 5; bold font indicates probability <.05.
*Spiritual Practices were: Meditation (minutes per day), Spiritual Awareness Practice (times per day), and Journaling (times per week).
**MEQ: Mean total score of the Mystical Experience Questionnaire (MEQ30).
***This participant-rated measure is a composite total score of the 6 subscales in Table 5 that assessed positive effects attributed to psilocybin session experiences.

Open-ended clinical interview at the 6-month follow-up

An open-ended clinical interview at the final follow-up visit was used to obtain spontaneous reports of possible persisting adverse events. There were no reports of bothersome or clinically significant persisting perception phenomena sometimes attributed to psychedelic use. Likewise, there were no reports of any non-study use of psychedelics since study enrollment. All 75 volunteers appeared to continue to be psychiatrically healthy, high-functioning, productive members of society.

Adverse effects

No serious adverse events attributed to psilocybin administration or the study procedures occurred. A number of adverse events occurred during psilocybin sessions, none of which was deemed to be serious. Consistent with previous research (Griffiths *et al.*, 2006, 2011, 2016), there were transient moderate increases in systolic and/or diastolic blood pressure after psilocybin. In one participant, diastolic blood pressure was elevated (126 mmHg) about an hour after psilocybin administration in the first session. The increase met protocol criteria for administration of sublingual nitroglycerin. The session was completed uneventfully. Although this participant reported that the session experience was positively meaningful and expressed a desire to continue with the study, the participant was discontinued from further participation.

Discussion

The present study with psilocybin extends a large descriptive literature on non-drug and psilocybin-occasioned transformative mystical- and insightful-type experiences (i.e. quantum change experiences, Miller, 2004) by using a prospective experimental design to test for enduring positive changes on well-validated trait measures of prosocial attitudes and behaviors, psychological functioning, and ratings of the participant by community observers. The rigorous double-blind design, which minimized expectancy effects, showed that psilocybin-occasioned mystical experience contributed significantly to the enduring positive changes. The present study results contrast those from previous studies of psilocybin (Darling *et al.*, 2004; Doblin, 1991; Griffiths *et al.*, 2008; 2011; Leary *et al.*, 1963; Pahnke, 1963; Studerus *et al.*, 2011) and the classic psychedelic LSD (McGlothlin *et al.*, 1967; Weil *et al.*, 1965) in healthy volunteers, which have provided little evidence of enduring positive changes on well-validated trait measures of disposition. This difference seems likely due to the experimental context of the present study, which provided encouragement for engagement in a nonsectarian program of meditation and other practices that emphasized the integration of spiritual values in daily life (e.g. prosocial values, self-knowledge through examining the nature of mind, and cultivating a sense of wonder).

Effects of psilocybin dose

Effects of psilocybin dose on session days

The time-course and profile of acute psilocybin effects were consistent with previous studies that have administered these doses of psilocybin to healthy volunteers under similar conditions (Griffiths *et al.*, 2006, 2011). Comparing the low-dose group with each of the two high-dose groups, psilocybin modestly increased blood pressure and heart rate and significantly affected a range of measures assessed by guides during sessions and by participants immediately after sessions (Tables 2 and 3). The profile of these acute psilocybin effects included perceptual changes (e.g. visual pseudo-hallucinations, illusions, and/or synesthesia), labile moods (e.g. feelings of transcendence, grief, joy, and/or anxiety), and cognitive changes (e.g. sense of meaning, insight, and/or ideas of reference).

In the high-dose conditions, 20 mg/70 kg was administered in session 1 followed by 30 mg/70 kg in session 2. The rationale for administering the doses in the ascending sequence was based on previous research suggesting that ascending doses are more likely to than descending doses to produce long-lasting positive changes in attitudes, behavior, and remembered mystical-type experiences (Griffiths *et al.*, 2011). Peak blood pressure was very modestly higher after the 30 vs. 20 mg/70 kg psilocybin dose but there were no significant differences between these doses on rating by guides during sessions or in participant ratings at the end of the session. It is possible that the fixed sequence of doses contributed to a failure to detect significant differences in acute subjective effects between the two doses.

Spiritual practices at 6 months

The study did not provide evidence that psilocybin dose affected engagement with spiritual practices. As expected, compared with the two standard spiritual support conditions, participants in the high spiritual support condition showed greater engagement with the three primary spiritual practices that were taught and encouraged during the guide-participant and dialogue-group meetings (Table 4 and Figure 4). For the last 4 months of the study, participants in the high-support condition reported average rates of meditation (19.3 minutes per day), spiritual awareness practice (5.2 times per day), and journaling (4.4 times per week) that were about double those reported in the standard-support groups. Likewise, the proportion of volunteers meditating daily, doing spiritual practices daily, or journaling daily was generally significantly higher than that in the two standard-support groups. However, the LD-SS and HD-SS groups were not significantly different on any of these six measures, indicating that, under the conditions of the study, psilocybin did not facilitate engagement with these spiritual practices.

Persisting effects attributed to psilocybin assessed at 6 months

Consistent with a previous study (Griffiths *et al.*, 2011), compared with the low-dose group, the high psilocybin dose groups showed greater increases in persisting positive effects that participants attributed to their psilocybin session experiences (Table 5 and Figure 5). The domains of positive changes were: attitudes about life, attitudes about self, mood, altruism/positive social effects, behavior, and increased spirituality. Also relative to the low-dose group, the two high-dose groups attributed significantly greater personal meaning, spiritual significance, and change in well-being or life satisfaction to the psilocybin experience. Similar significant differences between the low-dose group and two high-dose groups were also shown on the percentage of each group providing strong endorsements of personal meaning, spiritual significance, and change in well-being or life satisfaction (Table 5 and Figure 5).

Longitudinal measures assessed at 6 months

The most intriguing assessments in this study were a series of longitudinal measures, some of which are well-validated trait measures of psychological well-being, prosocial disposition, and spiritual worldview (Table 6). In contrast to prior psilocybin research with healthy volunteers which has generally not demonstrated enduring changes such measures (Griffiths *et al.*, 2008), the present study showed generally large significant effects of psilocybin dose across a range of longitudinal measures (Table 6; Table S2 shows corresponding effect sizes). Specifically, the effect of psilocybin dose is shown by comparing the LD-SS group with the HD-SS group. Of the 23 longitudinal measures in Table 6, the HD-SS group was significantly different from the LD-SS group on 14 measures, all in the expected direction. Furthermore, within-group analysis showed that change from baseline (6-month minus baseline score) were significant on only one of 23 measures in the LD-SS group in contrast to 17 of 23 measures in the HD-SS group.

Contrary to popular beliefs that psychedelic experiences lead to rejection of traditional worldviews (Stevens, 1987), in the current study, the life value of Tradition on the Schwartz Value Scale increased significantly from baseline to 6 months in the HD-HS group and was significantly higher in this group than the LD-SS group at 6 months. This subscale comprises items assessing respect for tradition, moderation of feelings and action, humility, accepting life's circumstances, and holding religious belief and faith. It is plausible that administering psilocybin in the context of encouraging spiritual practices accounts for this effect, which is consistent with the observation that indigenous sacramental use of psilocybin-containing mushrooms, peyote, ayahuasca and other classic psychedelic-containing substances is often strongly grounded in cultural traditions (Schultes *et al.*, 1998).

In the present study, the personality domain of Openness increased from screening to 6 months in the HD-HS group but not in the HD-SS or LD-SS groups. Further, there were no between-group differences in Openness at 6 months. Further analyses of these data (not presented) did not show significant relationships between several measures of mystical-type experience and changes in Openness. These findings contrast with the results from a previous analysis that showed that psilocybin-occasioned mystical experience was associated with increases in Openness from screening to 1-2 months and to 14 months after psilocybin (MacLean *et al.*, 2011). Increases in Openness have been shown 2 weeks after administration of LSD in healthy individuals (Lebedev *et al.*, 2016). Another study showed that increases in Openness predicted greater reduction in post-traumatic stress disorder symptoms among individuals receiving MDMA-assisted psychotherapy (Wagner *et al.*, 2017). The failure to observe significant increases in Openness in the current study may be attributable to engagement in the program of spiritual practices or to some other aspect of the study design.

Evidence that high support for spiritual practices increased both the acute and enduring effects of psilocybin

Session day effects

On several measures that were assessed on session days, the effects of the high dose of psilocybin were greater in the high spiritual practices support group than in the standard-support groups. Guide ratings of tearing/crying during the session and participants scores on the Mysticism Scale (total score and two subscales) were significantly higher in the HD-HS vs. HD-SS groups (Tables 2 and 3). Furthermore, on other participant-rated measures thought to reflect aspects of mystical-type experience (total scores and subscale scores of the MEQ30, and the Oceanic Boundlessness subscale of the 5D-ASC) the HD-HS group was numerically higher than the HD-SS group. These results contrast with the subjective ratings unrelated to mystical experience (Table 3), for which there were no significant differences or consistent trends between the two high-dose groups. The higher ratings on measures of mystical-type experiences in the HD-HS vs. the HD-SS group likely reflects that, before the first session, the high-support group received about twice as much meeting time with guides, with the majority of this extra time focused on discussion of and support for spiritual practices.

Persisting effects attributed to psilocybin assessed at 6 months

As with measures of mystical experience assessed on psilocybin session days, there was evidence for the HD-HS group showing greater effects than the HD-SS group. Significant differences were shown on altruism/positive social effects, positive behavior change, and increased spirituality, as well as ratings and percentage of strong endorsements of spiritual significance (Table 5, Figure 5). Strikingly, more than half (56%) of participants in the high spiritual support condition rated their experience in one or both psilocybin sessions as the single most spiritually significant experience of their life, with 96% rating it as among the top five most spiritually significant experiences. These results indicate that administering psilocybin in a context of high support for spiritual practices increases both the reported spiritual significance of the experience per se and the attribution to it of increased spirituality.

Longitudinal measures assessed at 6 months

As with measures of mystical experience assessed on session days and persisting positive effects attributed to psilocybin at 6 months, the longitudinal measures provide evidence for greater effects in the HD-HS group than the HD-SS group (Table 6 and Figure 6). Across groups, the HD-HS group showed numerically greater effects than the HD-SS group on 22 of the 23 measures, and showed statistically significant differences on seven of 23 measures. Furthermore, the HD-HS group differed significantly from the LD-SS group on all 23 measures, in contrast to the HD-SS group, which differed from the LD-SS group on 14 of 23 measures. These measures included positive changes in interpersonal closeness, gratitude, life meaning/ purpose, forgiveness, death transcendence, daily spiritual experiences, religious faith and coping, sanctification of life strivings, as well as ratings of participants by community observers. The effect sizes for these comparisons were quite large (mean Cohen's d=1.0 across all 23 measures, Table S2). Finally, within the HD-HS group, 6-month scores were significantly different from baseline on 20 of 23 measures (compared with 17 significant differences from baseline in the HD-SS group).

Relationship of spiritual practices and psilocybin-occasioned mystical experience to outcome measures

Prior research suggests an important role of psilocybin-occasioned mystical experience in the observed enduring positive changes in psychological well-being, prosocial disposition, and spiritual worldview (Garcia-Romeu *et al.*, 2014; Griffiths *et al.*, 2008, 2016; Ross *et al.*, 2016). In the present study, hierarchical regression analysis was used to examine the relationship of mystical experience and specific spiritual practices to the various outcome measures that showed between-group differences at 6 months (Table 7). The measure of mystical experience used for this analysis was the mean total score on the Mystical Experience Questionnaires (MEQ30) that were completed immediately following the two psilocybin sessions (4 and 5 months before the 6-month follow-up). Spiritual practices were assessed at the 6-month assessment with a questionnaire in which participants retrospectively rated over the past 4 months the three spiritual practices that were taught and encouraged during the study (minutes per day of mediation; times per day of spiritual awareness practice; times per week of spiritual journaling). When mystical experience alone was entered into a regression model, it accounted for a significant proportion of variance in all 19 outcome measures studied. In a separate hierarchical regression analysis, when the three spiritual practices were entered first into the regression model, they accounted for a significant proportion of the variance in 13 of 19 outcome measures studied. However, when mystical experience was subsequently entered into the model, it accounted for a significant proportion of variance in 18 of 19 measures after accounting for the impact of spiritual practices. For the overall regression model, meditation was significant on six measures (Faith Maturity Scale, Daily Spiritual Experience Scale, Forgiveness-benevolence motivations, Forgiveness-avoidance motivations, Observer-rated spiritual and religious sentiments, and Participant retrospective rating of the personal meaning of the session experiences); spiritual awareness practices were significant on two measures (Daily Spiritual Experience Scale, and Observerrated changes in behavior and attitudes); and journaling was significant on one measure (Observer-rated changes in behavior and attitudes).

Overall, these results suggest that both mystical experience and spiritual practices contribute to positive outcomes, with mystical experience making a substantially greater contribution. The fact that the measure of mystical experience preceded the assessment of outcome measures by 4-5 months strengthens the interpretation that mystical experience and/or its neurophysiological or other correlates are likely determinants of the enduring positive attitudinal, dispositional, and behavioral effects of psilocybin when administered under spiritually supported conditions.

It is interesting that a previous study with a relatively high dose (200 µg) of LSD, a different classic psychedelic, produced only moderate increases in total mystical experience scores (MEQ30), with only 12.5% of participants meeting criteria for a complete mystical experience (Liechti *et al*., 2017). Whether this lower rate of mystical experience reflects pharmacodynamic differences between psilocybin and LSD, the use of a relatively lower dose of LSD than psilocybin, and/or differences between the studies in set, setting, or participant characteristics is unknown (Barrett and Griffiths, 2017). Future research should directly compare LSD and psilocybin within subjects, ideally using procedures to minimize expectancy effects.

There was little evidence that the standard-support intervention alone affected longitudinal measures at 6 months. Of the 23 longitudinal measures (Table 6), only one measure in the LD-SS group showed a significant difference from baseline (immediately after study enrollment) to 6 months. Furthermore, across the longitudinal measures shown in Figures 6 and 7, the LD-SS group tended to be similar or lower than comparison data (e.g. norms) from previous studies. The absence of robust effects of the standard-support intervention contrasts with previous studies that showed a more intensive 8- or 9-session program using a similar intervention resulted in a variety of positive changes in spirituality, well-being, self-efficacy, and mental health outcomes (Flinders *et al*., 2007; Hedberg *et al*., 2006; Oman *et al*., 2006, 2008a,b). The lack of greater efficacy for the standard-support intervention in the present study was likely due to the minimal level of teaching and support provided to the LD-SS group.

Experimental design strengths and limitations

Strengths of the present study include the double-blind design, the use of a very low (possibly inactive) psilocybin dose as a control, and instructions to participants and guides, all serving to obscure the actual dose conditions and thereby minimizing participant and guide expectancy effects. This strategy has been used in previous psilocybin research (Griffiths *et al*., 2016). In the present study, the effects of very low dose of psilocybin (1 mg/70 kg) were compared with the high-dose conditions. The low dose was below a dose (3.15 mg/70 kg) that did not produce statistically significant effects in a previous study (Hasler *et al*., 2004). Participants and guides did report some psilocybin-like effects after the very low dose (e.g. Tables 2, 3, and 5), as might be expected under conditions in which participants (most of whom were psychedelic-naive) had been told they would receive psilocybin. For instance, three of 25 (12%) of participants in the low-dose condition rated their psilocybin session experiences to be among the five most spiritually significant of their lives.

Although the low-dose condition served as an important comparison to the high-dose conditions, in absence of a true placebo-dose condition, it is not possible to determine if the very low dose was pharmacologically active.

The integrity of blinding the guides to the study conditions was assessed with a post-study questionnaire that asked guides about their understanding of study drug and dose conditions. The finding that most guides made incorrect inferences about drug or dose conditions suggests substantial success of the blinding conditions. Guides were not required to make guesses about drug conditions after each session because we did not want to make this a focus of interest for guides. However, the absence of such guide ratings on each session precludes drawing a stronger conclusion about the success of blinding guides to study conditions.

The experimental design of the present study can be viewed as representing 3 of 4 cells of a balanced 2×2 design with dose (low dose vs. high dose) and spiritual support (standard support vs. high support) as factors. The fourth cell of a completely balanced design would be the low-dose high-support condition. Addition of that group would have permitted evaluation of the effects of high support independent of psilocybin. Although we considered the benefits of the balanced 2×2 design, we decided against it because of substantially increased study costs and because of concern that participants in this group, who receive only a low dose of psilocybin, might be less likely to comply with the more intensive schedule of participant-guide and dialogue-group meetings required in the high-support condition.

Additional limitations of the present study were the homogeneity of the participant population (predominately White, college educated, and employed) and the absence of brain-based or physiological measures of change or task-based measures such as assessment of implicit bias, emotion regulation, or social behavior. Finally, because the high-support condition involved group discussion of both spiritual practices and psilocybin experiences, the effect of group discussion of spiritual practice alone cannot be determined.

Conclusion

Although previous research shows that psilocybin, under appropriate conditions, can reliably occasion mystical-type experiences to which participants frequently attribute enduring positive changes in well-being and worldview, there has been little evidence from studies in healthy volunteers that psilocybin produces enduring changes on well-validated trait measures of disposition or personality. In the present study, psilocybin was administered in the context of undertaking a nonsectarian program of meditation and other spiritual practices that emphasized integration of spiritual values in daily life. The study showed robust interactive positive effects of psilocybin dose and added support for spiritual practices on a wide range of longitudinal measures at 6 months including interpersonal closeness, gratitude, life meaning/purpose, forgiveness, death transcendence, daily spiritual experiences, religious faith and coping, and rating of participants by community observers. Analyses suggest that the determinants of these effects were the intensity of the psilocybinoccasioned mystical experience and the rates of engagement with meditation and other spiritual practices. Most broadly, as a model system for studying so-called quantum change experiences, which have been described for centuries but which have eluded rigorous prospective experimental analysis, further investigation of psilocybin-occasioned experiences may have broad implications for the development of drug and non-drug interventions in both therapeutic and nontherapeutic applications in order to engender enduring positive trait-level changes in attitudes and behavior and in healthy psychological functioning.

Acknowledgements

The authors thank Frederick Reinholdt, M.S., Albert Garcia-Romeu, Ph.D., Daniel Evatt, Ph.D., Haley Sweet, Rosemary Flickinger and 13 other staff members for their roles as session guides. We also thank David Nichols, Ph.D. for synthesizing the psilocybin, Linda Felch M.A. for statistical analyses, Dr. Annie Umbricht for medical management, and Dr. David Addiss and Wayne Ramsey of the Fetzer Institute for help in scientific development and administrative support of this study. We are also grateful to Drs. Kenneth Pargament, Doug Oman, and Ralph Hood for helpful comments on the design of the study.

Declaration of conflicting interests

The author(s) declared the following potential conflicts of interest with respect to the research, authorship, and/or publication of this article: Roland Griffiths is on the Board of Directors of the Heffter Research Institute. Robert Jesse, convener of the Council on Spiritual Practices, participated in designing the study and writing the manuscript, but was not involved in data collection, analysis, or interpretation.

Funding

The author(s) disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: Conduct of this research was primarily supported by grants from the Fetzer Institute and the Council on Spiritual Practices. Some support was also provided by the Heffter Research Institute. Effort for Roland Griffiths, Ph.D. in writing this paper was partially provided by NIH grant RO1DA03889.

Abstract

Plant-based psychedelics, such as psilocybin, have an ancient history of medicinal use. After the first English language report on LSD in 1950, psychedelics enjoyed a short-lived relationship with psychology and psychiatry. Used most notably as aids to psychotherapy for the treatment of mood disorders and alcohol dependence, drugs such as LSD showed initial therapeutic promise before prohibitive legislature in the mid-1960s effectively ended all major psychedelic research programs. Since the early 1990s, there has been a steady revival of human psychedelic research: last year saw reports on the first modern brain imaging study with LSD and three separate clinical trials of psilocybin for depressive symptoms. In this circumspective piece, RLC-H and GMG share their opinions on the promises and pitfalls of renewed psychedelic research, with a

focus on the development of psilocybin as a treatment for depression.

The therapeutic potential of psychedelic drugs: tempered optimism (RLC-H)

"*Your assumptions are your windows on the world. Scrub them off every once in a while, or the light won't come in.*"
(Isaac Asimov, 1919-1992)

A brief history of psychedelic research

Psychedelic drugs (*Psychedelic* is a neologism that combines the words psychē (ψ υ χ ή, 'soul') and dēloun (δ η λ ο ῦ ν, 'to make visible, to reveal'), to denote 'mind-revealing' in reference to the category of drugs in question. I use the term in preference to 'hallucinogens' due to the latter's arguably misleading emphasis on these compounds' hallucinogenic properties. When using the term 'psychedelics' I refer to those compounds with appreciable serotonin 2A receptor agonist properties that can alter consciousness in a marked and novel way. LSD can be considered the prototypical or 'reference-standard' psychedelic.) awakened a significant cultural zeitgeist in mid-twentieth century (Stevens, 1987, see Table 1). Catalyzed by early reports on the unique potency and remarkable subjective effects of lysergic acid diethylamide (LSD) in the early 1950s, psychedelics, and particularly LSD, became widely used by psychologists and psychiatrists in research and clinical practice, with tens of thousands of patients estimated to have been treated with 'psychedelic psychotherapy' over a period of about 15 years (Grinspoon and Bakalar, 1979). From the mid-60s, psychedelic research was increasingly prevented from having the capacity to inform and potentially advance thinking and practice in psychology and psychiatry, but as popular and countercultural movements increasingly embraced the drugs, their societal impact skyrocketed (Grinspoon and Bakalar, 1979; Lee and Shlain, 1992; Stevens, 1987).

Table 1 Notable Landmarks of Mid-Twentieth Century Psychedelic Research Plus Events of Cultural Significance

Year	Landmark	References
1943	LSD's psychoactive effects discovered by Albert Hofmann (16th and 19th April)	Hofmann, 1980
1947	Werner Stoll publishes first paper on psychological effects of LSD in humans	Stoll, 1947
1950	First English language publication on LSD	Busch and Johnson, 1950
c. 1953	ACNP Founding president Joel Elkes (President in 1961) publishes on LSD after openly self-experimenting with it	Bradley *et al*, 1953; Roberts, 2008
1954	Aldous Huxley's 'The Doors of Perception' published: documents mescaline self-experiment	Huxley, 1954
1956	Term 'psychedelic' coined by Humphrey Osmond in communication with Aldous Huxley	Huxley, 1980
1957	Term 'magic mushrooms' coined by LIFE magazine	Wasson, 1957
1958	Identification of psilocybin in magic mushrooms by Albert Hofmann	Hofmann *et al*, 1958
1959	Closed conference held in Princeton on 'the use of LSD in psychotherapy', Jonathan Cole attends, an early ACNP president	Abramson, 1959
1960	First major European conference on psychedelics; Sidney Cohen publishes positive meta-analysis on LSD safety	Passie, 1996; Cohen, 1960
1961	Jonathan Cole (ACNP president 1965-66) expresses 'very mixed feelings on psychedelic research' as critical commentaries emerge	Mangini, 1998
1962	The Marsh Chapel or 'Good Friday' experiment conducted at Harvard under Timothy Leary's supervision but without institutional approval	Pahnke, 1966; Mangini, 1998

1963	Leary dismissed from Harvard; Aldous Huxley and JFK die (both on 22nd November)	Stevens, 1987
1964	Cole takes 'sober look' at psychedelics in JAMA; discussions on LSD take center stage at 1964 APA meeting; Ken Kesey travels across US taking LSD with 'Merry Pranksters'	Mangini, 1998; Cole and Katz, 1964; Stevens, 1987; Wolfe, 1968
1965	Sandoz stop manufacture of LSD and psilocybin	Stevens, 1987
1966	Prohibition of psychedelics and curtailment of research begins in US; Senator Robert Kennedy formally questions this move	Stevens, 1987; Lee and Shlain, 1992
1967	Timothy Leary declares 'turn on, tune in and drop out' at festival in Golden Gate Park	Stevens, 1987
1970	President Nixon signs Controlled Substances Act, LSD and psilocybin made Schedule 1	Stevens, 1987; Lee and Shlain, 1992

The present revival

Human psychedelic research fell into a 25-year hiatus before scientists in Germany (Hermle *et al*, 1992), the United States (Strassman and Qualls, 1994), and Switzerland (Vollenweider *et al*, 1997) began its revival. There now exists a foundation of human neuroimaging (Carhart-Harris *et al*, 2012a, 2016d; Daumann *et al*, 2010; Muthukumaraswamy *et al*, 2013; Palhano-Fontes *et al*, 2015; Preller *et al*, 2017; Riba *et al*, 2004, 2006; Vollenweider *et al*, 1997), psychology (Carhart-Harris *et al*, 2015, 2016c; Carter *et al*, 2007; Gouzoulis-Mayfrank *et al*, 2005; Griffiths *et al*, 2006; MacLean *et al*, 2011; Schmid *et al*, 2015), and psychopharmacology studies with psychedelics (Kometer *et al*, 2012; Preller *et al*, 2017; Valle *et al*, 2016; Vollenweider *et al*, 1998).

These foundational studies complement a small number of early phase clinical trials (Table 2). There are now positive preliminary reports on the safety and tolerability of psilocybin for obsessive compulsive disorder (Moreno *et al*, 2006), psilocybin, and LSD for end-of-life psychological distress (Gasser *et al*, 2014; Griffiths *et al*, 2016; Grob *et al*, 2011; Ross *et al*, 2016), psilocybin for alcohol (Bogenschutz *et al*, 2015), and tobacco addiction (Johnson *et al*, 2014) and ayahuasca (Osorio Fde *et al*, 2015) and psilocybin for major depressive disorder (Carhart-Harris *et al*, 2016a,b). An important caveat here, is that many of these trials report on small sample sizes and would best be described as 'safety and tolerability' studies by conventional standards (Schunemann *et al*, 2006), and while all of them do report outcomes consistent with potential efficacy, most have not been appropriately designed to demonstrate it conclusively. GMG critically discusses two of the largest and better designed trials in the next section (Griffiths *et al*, 2016; Ross *et al*, 2016).

Psychedelics for mental illness

Plant-based psychedelics have been used for hundreds if not thousands of years for holistic healing (Hofmann, 1980) and there remains an active culture of self-medication with psychedelics for mental health (Carhart-Harris and Nutt, 2010; Waldman, 2017). Contrary to the alarmist campaigning that so negatively affected perceptions of psychedelics after the 1960s, subjective (Carhart-Harris and Nutt, 2010, 2013; van Amsterdam *et al*, 2015), naturalistic/ observational (Bouso *et al*, 2012), and population-based data (Hendricks *et al*, 2015) indicate a positive association between psychedelic drug use and mental health, albeit with some important caveats, which will be discussed below.

Progressing to more controlled medical use, psychedelics piqued the interest of psychologists and psychiatrists in the 1950s, who noted early on that they may 'serve as new tools for shortening psychotherapy' (Busch and Johnson, 1950). A recent meta-analysis of 19 studies of psychedelics for mood disorders published between 1949 and 1973 found that 79% of patients showed 'clinically judged improvement' post treatment (Rucker *et al*, 2016). Moreover, a meta-analysis of studies of LSD for alcoholism performed in the 50-60s was similarly supportive of its potential (Krebs and Johansen, 2012). The absence of standardized diagnostic techniques, measures of symptom severity, and lack of randomization and control conditions in these studies needs to be properly heeded, but equally, it would be self-defeating to dismiss their findings outright.

Table 2 Clinical Trials Involving Psychedelics Published During the Present 'Second Wave' of Psychedelic Research

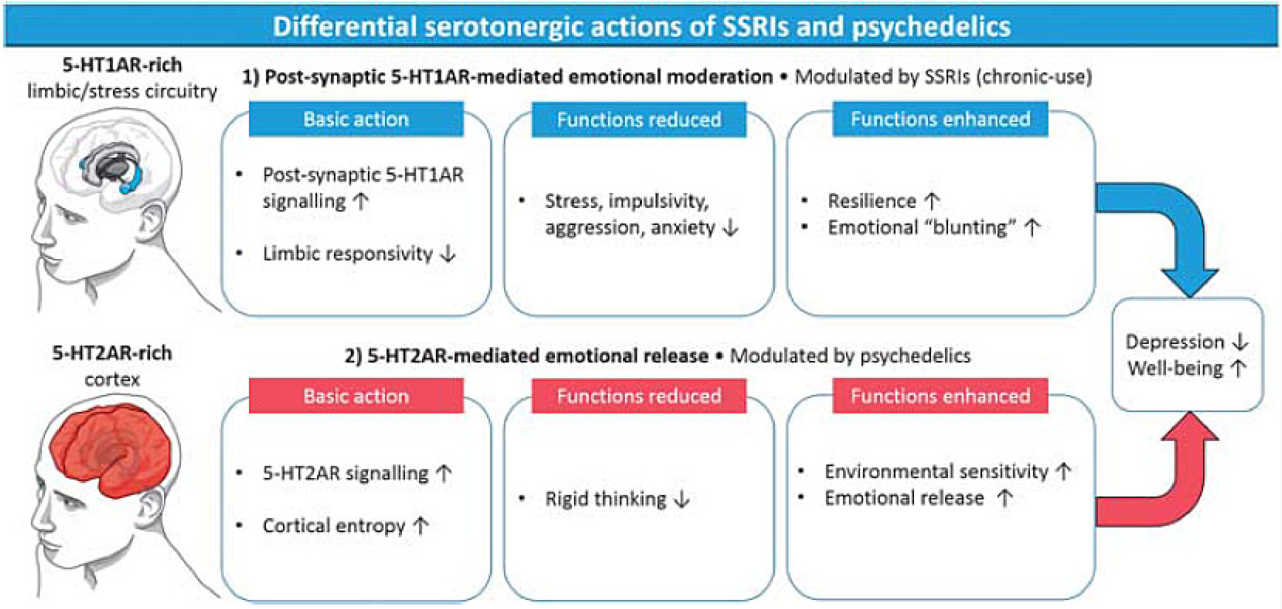
Study	Population/indication and sample size	Drug and design	Main efficacy outcome
Moreno *et al* (2006)	Obsessive compulsive disorder, *n*=9	Psilocybin: single-arm, within subjects, variable doses. Up to four doses of psilocybin	All patients showed improvements within 24 h of a treatment but no effect of dose
Grob *et al* (2011)	Anxiety and depression in endstage cancer, *n*=12	Psilocybin: DB-RCT, crossover, inert placebo. Single dose of psilocybin	Significant reductions in trait anxiety at 3 months and depression at 6 months
Johnson *et al* (2014)	Long-term chronic tobacco smoking, *n*=15	Psilocybin: open-label. Up to three doses of psilocybin after four CBT sessions	80% of sample abstinent at 6 month follow-up
Gasser *et al* (2014)	Anxiety related to life-threatening disease, *n*=12	LSD: DB-RCT, crossover, very low dose (VLD) LSD = control. Single dose of LSD	Significant decreases in state and trait anxiety *vs* VLD at 2 months and sustained for 12 months
Bogenschutz *et al* (2015)	Alcohol dependence, *n*=10	Psilocybin: open-label. Up to two doses after seven motivational therapy sessions	Significant decrease in drinking behaviors for up to 9 months
Osorio Fde *et al* (2015) and Sanches *et al* (2016)	Major depressive disorder (MDD), *n*=6+study extension to *n*=17	Ayahuasca: open-label. Single dose of ayahuasca	Significant decreases in depressive symptoms for up to 21 days
Carhart-Harris *et al* (2016a,b)	Treatment-resistant MDD, *n*=12+study extension to *n*=20	Psilocybin: open-label. Two doses of psilocybin	Significant decreases in depressive symptoms for up to 6 months
Ross *et al* (2016)	Anxiety and depression related to life-threatening cancer, *n*=29	Psilocybin: DB-RCT, crossover, niacin=active placebo. Single dose of psilocybin	Significant decreases in anxiety and depression *vs* niacin at 7 weeks (pre crossover) and sustained for 6.5 months
Griffiths *et al* (2016)	Anxiety and depression related to life-threatening cancer, *n*=51	Psilocybin: DB-RCT, crossover, VLD psilocybin=control. Single dose of psilocybin	Significant decreases in anxiety and depression *vs* VLD at 5 weeks (pre crossover). Effects sustained for 6 months

Abbreviations: DB-RCT, double-blind randomised controlled trial; VLD, very low dose; MDD, major depressive disorder; TRD, treatment-resistant depression.

The modern era of controlled research with psychedelics has seen the adoption of more careful experimental designs, together with a more critical approach to outcomes. In 2006, a double-blind randomized controlled (DB-RC) study compared the acute and longer-term psychological effects of single high doses of psilocybin (30 mg) and methylphenidate (40 mg) in healthy volunteers. Significantly, greater improvements in psychological well-being were observed after psilocybin than methylphenidate at the 2-month end point and more than half considered their psilocybin experience to be among the most personally meaningful experiences of their lives (Griffiths *et al*, 2006). Since then, the focus has shifted to include patients with symptoms of depression and anxiety. Three DB-RC trials have assessed the impact of a single dose of psilocybin on depressive symptoms in patients with life-threatening cancer (Griffiths *et al*, 2016; Grob *et al*, 2011; Ross *et al*, 2016) and an open-label trial of psilocybin for treatment-resistant depression (TRD) has been completed (Carhart-Harris *et al*, 2016a,b). All four studies, and particularly the three most recent, found rapid, marked, and enduring anti-anxiety and depression effects post psilocybin. Significant improvements in obsessive compulsive disorder symptoms (Moreno *et al*, 2006) and alcohol dependence with psilocybin (Bogenschutz *et al*, 2015), anxiety with LSD (Gasser *et al*, 2014), and depression with ayahuasca (Osorio Fde *et al*, 2015; Sanches *et al*, 2016) help supplement the case for psilocybin and inspire questions regarding the potential generalized therapeutic action of psychedelics.

Focusing on antidepressant action, psilocybin, and psychedelics more generally, share some similarities with conventional antidepressants (ie, serotonergic modulation); however, they also possess some important differences. Regarding similarities, an altered relationship with the environment may be critical to recovery with selective serotonin reuptake inhibitors (Belsky, 2016; Harmer and Cowen, 2013) and heightened sensitivity to the environment is a cardinal feature of the psychedelic state (Carhart-Harris *et al*, 2015; Hartogsohn, 2016; Kaelen *et al*, 2015), perhaps due to psychedelics' direct agonist action at the 5-HT$_{2A}$R (Dressler *et al*, 2016; Fiocco *et al*, 2007; Jokela *et al*, 2007). Regarding differences, the chronic antidepressant action of SSRIs includes reduced limbic responsiveness and emotional moderation or blunting, likely via post-synaptic 5-HT$_{1A}$ receptor signaling (Cowen and Browning, 2015; Deakin and Graeff, 1991; McCabe *et al*, 2010); this contrasts with the greater role for 5-HT$_{2A}$R signaling with psychedelics, and emphasis on emotional release

(Carhart-Harris *et al*, 2012b; Roseman *et al*, 2016; Watts *et al*, 2017). Contrasting approaches to emotion may be a fundamental difference between the SSRI and psychedelic treatment models (Figure 1).



Differential serotonergic actions of SSRIs and psychedelics
5-HT1AR-rich
limbic/stress circuitry
1) Post-synaptic 5-HT1AR-mediated emotional moderation • Modulated by SSRIs (chronic-use)
Basic action
• Post-synaptic 5-HT1AR signalling ↑
• Limbic responsivity ↓
Functions reduced
• Stress, impulsivity, aggression, anxiety ↓
Functions enhanced
• Resilience ↑
• Emotional "blunting" ↑
Depression ↓
Well-being ↑
5-HT2AR-rich
cortex
2) 5-HT2AR-mediated emotional release • Modulated by psychedelics
Basic action
• 5-HT2AR signalling ↑
• Cortical entropy ↑
Functions reduced
• Rigid thinking ↓
Functions enhanced
• Environmental sensitivity ↑
• Emotional release ↑

Figure 1 A bipartite model of serotonergic functioning focused on the effects of post-synaptic 5-HT$_{1A}$R and 5-HT$_{2A}$R signaling. The more pronounced effects of chronically used SSRIs on post-synaptic 5-HT$_{1A}$R signaling is hypothesized to relate to their anti-stress, pro-coping properties but also their tendency to moderate or 'blunt' emotional responsiveness. The direct 5-HT$_{2A}$R agonist properties of psychedelics are hypothesized to relate to their proclivity to enhance sensitivity to the environment as well as facilitate emotional release, which, when combined with psychological support, is hypothesized to be therapeutically potent.

In my opinion, if the science is allowed to progress without the kind of political interference that has hindered it in the past, psilocybin with psychological support (PwPS) will become an early option in the treatment of depression. I predict that PwPS will be found to have important areas of superiority over current early interventions such as SSRIs and CBT. Specifically, PwPS's rapid and enduring action with minimal exposure, positive side-effect profile, and specific therapeutic action - working to address rather than suppress or side-step aversive memories and emotions, may set it apart from the alternative, largely 'palliative' treatment options for major depression.

> "*That is the essence of science: ask an impertinent question, and you are on the way to a pertinent answer.*"
> (Jacob Bronowski, 1908-1974)

Another consideration is that chronic antidepressant medication strategies appear to have a muting effect on psilocybin's acute and putative antidepressant effects (Bonson *et al*, 1996; Bonson and Murphy, 1996), implying that treating medication-heavy, treatment-resistant depressed patients with psilocybin will be especially challenging (Carhart-Harris *et al*, 2016a,b). Medication discontinuation would likely be required prior to receipt of the psychedelic and this often requires careful management (Baldwin *et al*, 2007).

The therapeutic potential of psychedelic drugs; Upbeat pessimism (GMG)

> "*What Leary took down with him was the central illusion of a whole life-style that he helped to create... a generation of permanent cripples, failed seekers, who never understood the essential old mystic fallacy of the Acid Culture: the desperate assumption that somebody, or at least some force, is tending the Light at the end of the tunnel.*"
> (Hunter S Thompson. Fear and Loathing in Las Vegas, 1971)

Finding signal amidst the psychedelic noise

As a clinician long committed to the view that neuroscience should inform psychiatry, psychedelics have always looked like a serious opportunity. Their structure and pharmacology inspired a generation of neurochemists to understand neurotransmitters and their receptors. And, the very idea that drugs could usefully change the experience of distressed patients with psychiatric disorders underpinned the revolution in psychopharmacology in the three decades from 1950. However, the 'illegal' status of psychedelics stopped serious research in humans until quite recently, as RLC-H has explained.

So, can psychedelics take us back to the future? I understand the appeal that RLC-H feels for their potential. However, the difficulty in finding a medical role for psilocybin must not be underestimated. It is worth reflecting on what we have learned from the very recently published clinical trials. Their strengths and their weaknesses define the challenge. As for the strengths, when two very similarly designed but independent studies of the effects of any pharmacological agent give the same result, it is encouraging. Accordingly, the two studies in patients with cancer experiencing enduring psychiatric symptoms and given psilocybin or a comparator (Griffiths *et al*, 2016; Ross *et al*, 2016) deserve to be taken seriously. However, there have to be caveats. Are we confident that we understand the patient population? Did the trial design allow a clear question to be asked and were the outcomes meaningful?

The patient population

In the choice of patient group, why cancer patients? Ross *et al*. (2016) suggested that a domain of distress they call existential/spiritual well being is particularly relevant to depression in cancer while Griffith *et al*. (2016) emphasize that evidence for efficacy of conventional medication or psychotherapy is poor or even negative.

Symptoms of both depression and anxiety are relatively common in cancer patients. But, they are often not very severe and in fact patients may choose not to seek help in their treatment (Baker-Glenn *et al*, 2011). In a case series of 128 patients attending for their first session of chemotherapy for cancer, only about 20% indicated they would appreciate psychological help for distress, depression, or anxiety. Of these, most indicated they would appreciate the opportunity to speak to someone - but only one suggested a psychiatrist.

Significant depressive symptoms can occur in cancer patients of course and active screening of a large consecutive cohort suggested about 8% met criteria for a major depressive episode (Sharpe *et al*, 2004) and many are not offered treatment. A subsequent trial in 200 such patients was conducted to compare a nurse intervention (which included antidepressant medication as an option and problem solving) with treatment as usual (Strong *et al*, 2008). There was a clinically significant and sustained impact of intervention on depressive symptoms (and on anxiety and fatigue): 68% of the treated group achieved remission compared with 45% of the comparator group (odds ratio 3 (confidence interval: 1.6-5.5).

Thus, the case for a particular unmet need in cancer patients is actually quite difficult to sustain. The idea that cancer diagnosis poses a particular threat to existential/ spiritual well-being in some patients may be correct but there is a risk that one recruits into trials people with a particular interest in psychedelic experience, who are hence predisposed to endorse its benefits. They may not be representative of cancer patients in general. In the published study where it is reported, the rate of previous use of hallucinogens was indeed high (55% in the Ross *et al*, 2016).

The trial design

In each of the two cancer studies, the design was a crossover, which compared, respectively, low-dose/high-dose psilocybin and niacin (placebo)/high-dose psilocybin. The subjective effects of the high dose consisted in heightened states of consciousness with marked emotional accompaniments (anxiety, tearfulness, and in a few cases, paranoid ideation). These effects were as expected, given the previous literature. It is difficult to see how blinding can be maintained because the subjective effects of drug were so florid. There was some uncertainty in the ratings by support staff, who supervised the sessions blind to dosing. However, overall one must assume the patients were usually unblinded by their experience on active drug. If so, it provided the kind of cue called a demand characteristic. That is anything that makes participants in an experimental study aware of what the experimenter expects to find or how participants are expected to behave. Such issues would also be difficult to avoid in judging outcomes, without great care in preserving raters to be blind.

The outcome measures

The outcome measures of both trials are self, community, and clinician reports. Thus, they are entirely subjective, as most studies of antidepressants and anxiolytics have been. The demand problem has been noted already for patients, but it will also be problematic for third-party reports if patients communicate their own unblinding at interview. But, just as for other studies, symptoms alone are a problematic way of assessing outcome. In other words, they are not highly proximal to the disease process as for example research domain criteria dimensions have been suggested to be. But, they are also not distal enough for assessing the functional value of treatment either. More objective measures are possible. One could objectively measure simple motor activity or geolocation. Geolocation is particularly simple to obtain entirely passively from mobile phones. The resulting measure of time at home for example correlates well with depression severity in depressed bipolar patients (Palmius *et al*, 2016). In cancer patients, there is the further domain of medical care, which is known to be complicated by co-morbid depression. An increase in adherence to treatment or even efficacy could result from really effective treatment. Greater objectivity should contribute more to the picture in future research of psilocybin's potential role. Nevertheless, for the moment, subjective response remains the regulatory standard against which psychotropic drugs will be measured.

Does the psilocybin experience really belong in medicine?

The unspoken assumption, which I think we both share, is that the use of psilocybin at this stage requires a medical justification. Certainly, it started in western society as a putative aid to psychotherapy, but of course, it has an older cultural history as a constituent of magic mushrooms. Many believed and believe that the justification for the use of such drugs lies in their capacity to open the doors of perception, as Aldous Huxley put it. On this view, access to such drugs should be a recreational right, like access to alcohol, cigarettes, and increasingly cannabis. As with cannabis, medical use may be expected to promote wider discretionary use for any reason. Some may still regard this as a red light for the development of medical indications.

However, there is an important corollary to the continuing illegal status of psychedelics. It seems to me paradoxical, even incredible, that such drugs should not be available for medical use in conditions for which euthanasia is already available. In Belgium, neuropsychiatric disorders were first reported under euthanasia legislation in 2004/5. Of the first such 100 patients considered for euthanasia between 2007 and 2011, 58 had depression. Forty-eight of the total were accepted for euthanasia (35 completed) and six others had died by suicide within 12 months from the end of the study. Most patients were female, aged 40-60 years. Euthanasia for psychological suffering is similarly available in the Netherlands and Luxemburg (Thienpont *et al*, 2015).

So, I think we need psilocybin in medicine but we should not forget the failures of human logic, which mean we need high-quality clinical trials:

> "*All who drink of this remedy recover in a short time, except those whom it does not help, who all die. Therefore, it is obvious that it fails only in incurable cases.*"
> (Galen in 180 AD)

How to move the field forward (GMG and RLC-H)

Our shared interest in the development of psychedelics, and particularly psilocybin, for medical use is a major point of convergence. There may be a subtle difference in our views of the so-called 'mystical' elements of the psychedelic experience, ie, both of us see the term 'mystical' as problematic - but whereas GMG views the acute 'psychedelic experience' as irrelevant to the clinical development of psychedelics, RLC-H sees it as a potentially exploitable component - especially as it has been shown to be predictive of long-term clinical outcomes (eg, in Johnson *et al*, 2014; Bogenschutz *et al*, 2015; Griffiths *et al*, 2016; Ross *et al*, 2016; Carhart-Harris *et al*, 2016a,b). Perhaps the most notable point of divergence, however, relates to the choice of patient population for the clinical development of psilocybin for depression. For GMG, the most obvious and relevant unmet need is treatment-resistant depression (see below), and while RLC-H accepts that treatment resistance is often the first port-of-call for the development of a novel intervention, he feels that unipolar depression more generally, will prove a better indication for this treatment. In his view, psilocybin will be safest, most effective, and easiest to implement, prior to the treatment-resistant stage of illness.

Focusing on treatment-resistant depression for the moment, however, we both recognize that a significant number of patients treated first line with either a SSRI or CBT fail to respond adequately (Gaynes, 2009). Persisting symptoms lead to enduring chronicity of depression, and there is no consensus in existing guidelines on what to do next. Moreover, the efficacy of secondary intervention is often modest and new medications can introduce new side effects. The duration of distress with TRD and its economic impact are considerable. We agree that TRD represents a valid point in the treatment pathway, where a single psychedelic intervention might find a place; however, RLC-H questions whether patients must wait until their depression is significantly stamped-in before psilocybin can be considered, and based on the speed and duration of treatment responses seen in the trials listed above, it seems reasonable to ask whether early intervention with psilocybin could be prophylactic - and there is also the issue of SSRIs obstructing the potential therapeutic action of psilocybin.

If it is to be TRD, however, then patient recruitment can be based on pre-existing criteria (Sackeim, 2001) and patients meeting them will not be rare and should not be excessively treatment resistant. As noted earlier, there is a significant challenge to the issue of continuing medication, most commonly with SSRIs. There is anecdotal evidence that psychedelic effects are largely attenuated by ongoing treatment with SSRIs (Bonson *et al*, 1996) and perhaps with other antidepressants (Bonson and Murphy, 1996). Downregulation of 5-HT$_{2A}$ receptors is a feature of many different first-line antidepressant drugs (Muguruza *et al*, 2014), as well as second-line antidepressant medications (eg, atypical antipsychotics) with significant 5-HT$_{2A}$R antagonist properties (Gray and Roth, 2001). Any trial would ideally be conducted in patients withdrawn from such drugs for at least 2 weeks or so, but we accept that this is not always straightforward (Baldwin *et al*, 2007).

Moving on from questions of the optimal patient population, both of us can see merit in a multiple dose trial comparing, for example, 1, 10 and 25 mg of psilocybin. Such a design seems to overcome some of the problems any trial of a psychedelic will face. The ethical problem of equipoise seems satisfactory because we really do not know which dose, if any, will be effective, and patients can enter the study knowing that whatever group they are allocated to, they will receive active drug. The omission of a strict placebo control would be pragmatic in this sense, as expectation and preparation would be standardized. We know the highest dose of psilocybin will likely unblind participants and the expectation of a possible placebo would complicate recruitment. An approximation to an inert placebo condition may be met with the 1 mg psilocybin arm, as such a dose is likely too low to produce appreciable subjective or physiological effects (Griffiths *et al*, 2016). The differences between a dose mainly producing perceptual distortion (10 mg) and one more capable of producing the more profound, putatively 'transformative' aspects of the psychedelic experience (25 mg) is also of scientific and clinical interest.

Comparing mechanisms and/or efficacy with an established treatment would be a next step to advance the evidence base for psilocybin for TRD. For example, psilocybin could be compared with ketamine since it has some similarities: rapid, single-dose efficacy, and obvious subjective effects during its infusion. Psilocybin's distinctive subjective effects and the implications of this for blinding would still remain a major challenge; moreover, as with ketamine, there will also remain the question of how much an acute response is sustained and whether a maintenance dose may be required.

The traditional view of the mechanism, whereby psilocybin works, emphasizes the importance of accompanying psychotherapy (Johnson *et al*, 2008; Richards, 2015). Accordingly, psychedelics administered without psychological support and/or a supportive environment may have limited antidepressant efficacy, and in very rare cases, could even worsen a patient's condition (Oram, 2014). We share the view that the presence of psychological support is an essential component of the psychedelic treatment model (Johnson *et al*, 2008) but we also recognize that the magnitude and nature of its contribution needs to be better defined and tested.

Pragmatically, we accept that minimizing the active psychological work of the therapy would be desirable (eg, therapy time is expensive) and scientifically, doing so would allow drug effects and dose to be better identified.

Critically however, any such therapy minimization should not be allowed to jeopardize patient safety (Johnson *et al*, 2008). A future challenge will be to learn how psychological interventions can maximize the advantages of the psychedelic state. For example, we can imagine how cognitive therapy, attentional-bias training and/or de-sensitization could be investigated with or without psilocybin assistance.

In other respects, a psilocybin trial is easier to conduct than studies requiring continuing adherence to a daily oral dose of an antidepressant. Exposure to the treatment can be completely controlled and follow-up can be relatively pragmatic. It seems logical to determine an early proximal end point to prove initial impact of treatment and then to follow subsequent illness course as comprehensively as possible. In this way, we will be able to determine time to supplementary treatment, document recovery of symptoms and function, and perhaps objectify improvement using a simple frictionless measure of activity-like geolocation (Palmius *et al*, 2016).

In the short term, there will also be a need to demonstrate cost effectiveness. The requirement for psychological support and/or a supportive environment could be a major limitation of the psychedelic treatment model. However, direct medical costs need to be netted off against the social and economic costs of illness.

In summary, a door has been opened for the medical repurposing of psychedelics. The possibility exists that drugs like psilocybin can meet a major unmet need in the treatment of psychiatric disorders. For GMG, treatment-resistant depression is the most logical place to start because of the uncertainty around the choice of next-step treatment after an SSRI fails, and while RLC-H accepts this (Carhart-Harris *et al*, 2016a,b), he looks forward to a time when an individual may receive psilocybin before the ruts of depression are allowed to deepen (Holtzheimer and Mayberg, 2011). Regardless of who the 'right' patient population might be eventually, a key challenge now is to design the optimal trial to demonstrate efficacy, agree its validity with regulatory authorities and fund it.

Funding and disclosure

GMG is a NIHR senior investigator; the views expressed are those of the author and not necessarily those of the NHS, the NIHR or the Department of Health. GMG holds a grant from Wellcome Trust, holds shares in P1vital and has in the past 3 years served as consultant, advisor or CME speaker for Angelini, MSD, Lundbeck (/Otsuka or /Takeda), Medscape, P1Vital, Pfizer, Servier and Shire. RLC-H is supported by the Alex Mosley Charitable Trust and his research has received support from the Beckley Foundation, as part of the Beckley-Imperial Research Programme. RLC-H and GMG are currently advising Compass Pathways, a commercial initiative to develop psilocybin as a medicine.

Acknowledgments

RLC-H would like to thank Samantha Strong for the illustrations contained in Figure 1.

Abstract

Psychedelic or consciousness-expanding drugs have been studied by Western scientific researchers as adjuncts to psychotherapy while their plant-based equivalents are used in traditional ceremonial context for healing and spiritual practice. Plant extracts from tobacco, coca, coffee and cannabis, used as sacraments in indigenous cultures have become recreational drugs in contemporary society. Research with consciousness-expanding or entheogenic substances such as MDMA, LSD and psilocybin has focused on their value as adjuncts to psychotherapy. The worldwide underground culture has adopted the use of hallucinogenic plants and fungi, such as psilocybe mushrooms, ayahuasca, iboga and peyote, in small group hybrid therapeutic-shamanic ceremonies as well as large scale events such as raves. Core elements of such hybrid rituals are: the structure of a circle, a ritual space and altar of some kind, the presence of an experienced elder or guide, the use of eye-shades or semi-darkness and the cultivation of a respectful, spiritual attitude.

Keywords: Entheogens, psychedelics, hallucinogens, consciousness expansion, MDMA, psilocybe mushrooms, ayahuasca, LSD, hybrid rituals, shamanism.

Introduction

My research interest in the potentials of psychedelic drugs for the transformation of consciousness began when I was a graduate student at Harvard University in the early 1960s, studying with Timothy Leary and Richard Alpert (who later became Ram Dass). Subsequently, I became interested in the role of altered states of consciousness (induced by plants and other methods) in three great traditional systems of transformation - shamanism, alchemy and yoga. I have now come to regard shamanic or neo-shamanic ritual use of such plants, along with herbal medicine and organic farming, as part of a worldwide movement toward a more balanced and conscious relationship with the plant realm. In this essay, I review the role of psychoactive plant medicines and speculate on how they might be integrated into society in a healthy way.

There is a question that has troubled me, and no doubt others, since the earlier heyday of psychedelic research in the 1960s, when many groups and individuals were preoccupied with the problem of assimilating new and powerful mind-altering substances into Western society. The question, simply stated, was this: how did the American Indians succeed in integrating the use of peyote into their culture, including its legal use as a sacrament to this day, when those interested in pursuing consciousness research with drugs in the dominant white culture succeeded only in having the entire field made taboo to research, and any use of the substances a criminal offense punishable by imprisonment? The use of peyote spread from Mexico to the Northern Native American tribes in the latter half of the nineteenth century, and has found acceptance as a sacrament in the ceremonies of the Native American Church. It is recognized as one kind of religious ritual that some of the tribes practice; and it is acknowledged by sociologists for its role as an antidote for alcohol abuse.

This intriguing puzzle in ethnopsychology and social history was relevant to me personally, since I was one of the psychedelic researchers, who saw the enormous transformative potentials of "consciousness expanding" drugs, as we called them, and were eager to continue the research into their psychological significance. It would be fair to state that none of the early explorers in this field, in the fifties and early sixties, had any inkling of the social turmoil that was to come, nor the vehemence of the legal-political reaction. Certainly Albert Hofmann, the Swiss chemist who discovered LSD, an epitome of the cautious, conservative scientist, has testified to his dismay and concern over the proliferation of patterns of abuse of what he so poignantly called his "problem child" (*Sorgenkind*).

Thus resulted the strange paradox that the substances regarded as a social evil and a law-enforcement problem in the mainstream dominant culture are the sacrament of one particular sub-culture within that larger society. Since the surviving Native American cultures are older and in many ways ecologically more sophisticated than the cultures of the European invaders and settlers, the examination of the paradox posed above could lead to some highly interesting considerations.

The answer to the ethnopsychological puzzle became clear to me only after I started observing and participating in a number of other Native American ceremonies that did not involve the use of peyote - such as singing-healing circles, 'sweat lodge' and 'spirit dance' ceremonies. I noted what many ethnologists have reported: that these ceremonies were simultaneously religious, medicinal, and psychotherapeutic. The sweat lodge, like the peyote ritual, is regarded as a sacred ceremony, as a form of worship of the Creator; they are also practiced as a form of physical healing; *and* they are used for solving personal and collective psychological problems. Thus it was natural, for those tribes that took up peyote, to add this medium to the others they were already familiar with, as a ceremony that expressed and reinforced the integration of body, mind and spirit.

In the dominant white society by contrast, medicine, psychology and religious spirituality are separated by seemingly insurmountable paradigm differences. The medical, psychological and religious professions and established groups, each separately, were much too frightened by the unpredictable transformations of perception and worldview that psychedelic drugs seemed to trigger. Thus, the dominant society's reaction was fear, followed by prohibition, even of further research. None of the three established professions wanted these consciousness-expanding instruments, and neither did they want anyone else to be able to use them of their own free choice. The implicit assumption was (and is) that people are too ignorant and gullible to be able to make reasoned, informed choices as to how to treat their illnesses, solve their psychological problems, or practice their religion. The fragmented condition of our society is mirrored back to us through these reactions.

For most Native Americans and in indigenous societies in all parts of the world, healing, worship and problem-solving are all subsumed in the one way, which is the way of the Great Spirit, the way of Mother Earth, the traditional way. The integrative understanding given in the peyote visions, or in experiences with plant extracts like *ayahuasca* in South America or *iboga* in Central Africa, is not feared, but accepted and respected. Here the implicit assumption is that everyone has the capability, indeed the responsibility, to attune themselves to higher spiritual sources of knowledge and take responsibility for their own health-maintaining and spiritual practices. The purpose of ceremony, with or without medicinal substances, is regarded as a facilitating of such attunement. Indeed, the word "medicine" is used in Native American circles to refer to any substance, practice, even words, or persons - with a kind of integrative spiritual power.

The revival of interest in shamanic practices of healing and divination can be seen as expressions of a worldwide seeking for the renewal of a spiritual relationship with the natural world. Over the past two millennia Western civilization has increasingly developed patterns of domination and exploitation based on arrogant assumptions of human superiority. This dominator pattern has involved the gradual dis-enchantment and enormous destruction of non-human nature. By contrast, many indigenous people with shamanic practices have maintained beliefs and values that honor and respect the integrity, indeed the sacredness, of all of nature, in its infinite variety of manifestations. Their life-style includes rituals of remembrance of the living intelligences, called "spirits", inherent in the natural world.

In the modern worldview, such a recognition of "spirits" in nature, is considered beyond the pale of reason. 'Spiritual' and 'natural' are virtually considered opposites. However, those seekers who are again practicing the shamanic methods of earlier times and cultures are rediscovering that these methods are not at all incompatible with the curiosity and respectful knowledge-seeking of a scientific explorer or researcher. The revival of shamanic ritual practices and an animistic worldview can be seen as part of a worldwide human response to the degradation of ecosystems and the biosphere. These groups and individuals are expressing a new awareness, as well as a revival of ancient awareness of the organic and spiritual interconnectedness of all life on this planet.

Psychedelics as sacrament or recreation

Several observers, including Andrew Weil among others, have pointed out the historical pattern that as Western colonial society adopted psychoactive plant or food substances from native cultures, the pattern of use of such psychoactive materials *devolved* from sacramental to recreational. *Tobacco* was historically regarded as a sacred or power plant by Indians of North, Central and South America and is still so regarded by Native Americans. However, in the white Western culture, and in countries influenced by this dominant culture, cigarette smoking is obviously recreational, and tobacco addiction become a major public health problem. The *coca* plant, as grown and used by the Andean Indian tribes, was treated as a divinity, *Mama Coca*, and valued for its health- and energy-maintaining properties. The concentrated extract *cocaine* on the other hand is purely a recreational drug and its indiscriminate use as such has led to serious public health problems. In this, and other instances, desacralization of the plant-drug has been accompanied by criminalization. Even our most popular stimulant *coffee* is an example of this trend: Apparently first discovered and used by Islamic Sufis, who valued its stimulant properties for long nights of prayer and meditation, it became a fashionable recreational drink in European society in the 17th century, and was even banned for a while as being too dangerous. And *cannabis*, used by some sects of Hindu Tantrism as an amplifier of visualization and meditation and by manual laborers as a relaxant, has become the epitome of the recreational "high", associated with jail terms for simple possession.

Since sacramental healing plants were so rapidly and completely desacralized upon being adopted by the West's increasingly materialistic culture, it is not surprising that newly discovered synthetic psychactive drugs have generally been very quickly categorized as either recreational or narcotic - even those, like the psychedelics, whose effects are the opposite of "sleep-inducing". Concomitantly, as the indiscriminate and non-sacramental use of psychoactive plants and newly synthesized analogs spread, so did patterns of abuse and dependence. Predictably, established society reacted with prohibitions, which in turn furthered organized crime activities. This is so in spite of the fact that many of the original discoverers of the new synthetic psychedelics, people such as Albert Hofmann and Alexander Shulgin, are individuals of deep spiritual integrity. Neither they, nor the efforts of philosophers such as Aldous Huxley, Alan Watts and Huston Smith, or psychologists such as Leary, Alpert and many others, to advocate a sacred and respectful attitude towards these substances, were able to prevent the same profanation from taking place.

The later discovered phenethylamine psychedelic (also called *empathogenic*) MDMA provides an instructive example of this phenomenon. Two patterns of use seem to have become established during the 1970s: some psychotherapists and spiritually inclined individuals began to explore its possible applications as a therapeutic adjuvant and as an amplifier of spiritual practice. Another, much larger group of individuals began using it for recreational purposes, as a social "high" comparable in some respects to cocaine. The irresponsible and widespread use in this second category by increasing numbers of people understandably made the medical and law-enforcement authorities nervous. The predictable reaction occurred: MDMA was classified as a Schedule I drug in the United States, which puts it in the same group as heroin, cannabis and LSD, making it a criminal offense to make, use or sell, and sending a clearly understood taboo signal to pharmaceutical and medical researchers.

After Albert Hofmann had identified psilocybin as the psychoactive ingredient in the Mexican 'magic mushroom' (*Psilocybe mexicana*), he brought some of the synthesized psilocybin to the Mazatec shamaness María Sabina, in order to obtain her assessment of how close the synthesized ingredient was to the natural product. In doing so, he was following the appropriate path of acknowledging the primacy of the botanical over the synthetic. It has been suggested that for everyone of the important synthetic psychedelics, there is some natural plant that has the same ingredients, and that perhaps it should be our research strategy - to find the botanical "host" for the psychedelics emerging from the laboratory. Research on the shamanic use of the hallucinogenic morning glory seeds called ololiuhqui in ancient Mexico, which contain LSD analogs, has enabled a deeper understanding of the possibilities of this substance.

If Wasson, Hofmann and Ruck are correct in their proposal that an LSD-like ergot-derived beverage was used as the initiatory sacrament in Eleusis, the implications are profound. According to Rupert Sheldrake's theory of morphogenetic fields, rituals, like any patterned activity, gain their power through precise repetition of all the elements. One could suppose that by re-growing or re-hybridizing this particular plant, as it was used in ancient times, we could "tune in" to and re-activate the morphogenetic field of the Eleusinian Mysteries, the ancient world's most awe-inspiring mystical ritual.

There is no inherent reason why sacramental use and recreational use of a substance in moderation cannot co-exist. In fact, among Native Americans, tobacco often does play this dual role: after a sacred pipe ritual with tobacco and other herbs, participants may smoke cigarettes to relax. We know the sacramental use of wine, in the Catholic communion rite, and we certainly know the recreational use of wine. We are able to keep the two contexts separate, and we are also able to recognize when recreational use becomes dependence and abuse. One could envision similar sophistication developing with regard to psychoactive plant products. There could be recognized sacramental and therapeutic applications; and certain patterns of use might develop that were more playful, exploratory and hedonistic - and yet could be contained within a reasonable and acceptable social framework that minimizes harm.

The abuse of a drug in such a rational and sensible system would not be a function of who uses it, or where it originated, or its chemical classification - but rather the behavioral consequences in the drug user. Someone becomes recognized as an alcoholic, that is an abuser of alcohol, when their interpersonal and social relationships are noticeably impaired. There should be no difficulty in establishing similar abuse criteria for other psychoactive drugs.

Consciousness research with entheogens

In the field of consciousness research, the "set-and-setting hypothesis", which was first formulated by Timothy Leary in the early sixties, helps us to understand psychoactive drugs and plants as one class of triggers within a whole range of possible catalysts of altered states. The theory states that *the content of a psychedelic experience is a function of the set (intention, attitude, personality, mood) and the setting (interpersonal, social and environmental)*; and that the drug functions as a kind of trigger, or catalyst, or non-specific amplifier (To a lesser extent, the determining role of set-and-setting also applies to other psychoactive drugs such as the stimulants and tranquilizers). The hypothesis can also be applied to the understanding of any altered state of consciousness, when we recognize that other kinds of stimuli can be triggers - for example hypnotic induction, meditation technique, *mantra*, sound or music, breathing, sensory isolation, movement, sex, natural landscapes, a near-death experience, and the like.

An important clarification results from keeping in mind the distinction between a state (of consciousness) and a psychological trait; between state changes and trait changes. For example, psychologists distinguish between state-anxiety and trait-anxiety. William James, in his classic *Varieties of Religious Experience*, discussed this question in terms of whether a religious or conversion experience would necessarily lead to more "saintliness", more enlightened traits. This distinction is crucial to the assessment of the value or significance of drug-induced altered states. Only by attending to both the state-changes (visions, insights, feelings), *and* the longer-term behavioral or trait changes, can a comprehensive understanding of these phenomena be attained.

Having an insight is not the same as being able to apply that insight. There is no inherent connection between a mystical experience of oneness and the expression or manifestation of that oneness in the affairs of everyday life. This point is perhaps obvious, yet it is frequently overlooked by those who argue that, on principle, a drug could not induce a genuine mystical experience, or play any role in spiritual life. The internal factors, including preparation, expectation and intention, are the determinants of whether a given experience is authentically religious. Equally, intention is crucial to the question of whether an altered state results in any lasting personality changes. Intention is like a kind of bridge from the ordinary or consensus reality state to the state of heightened consciousness; and it also can provide a bridge from that heightened state back to ordinary reality.

This model allows us to understand why the same drug(s) could be claimed by some to lead to *nirvana* or religious vision, and in others could lead to perversion, violence and criminality. The drug is only a tool, or a catalyst, to attain certain altered states - which altered states being dependent on the intention. Further, even where the drug-induced state is benign and expansive, whether or not it leads to long-lasting positive changes is also a matter of intention or mind-set, as well as on-going practice.

The potential of psychedelic drugs to act as catalysts to a transformation into *gnosis*, or direct, ongoing awareness of divine reality, even if only in a small number of people, would seem to be of the utmost significance. Traditionally, the number of individuals who had mystical experiences has been very small; the number of those who have been able to make practical applications of such experiences has probably been even smaller. Thus the discovery of psychedelics, in facilitating such experiences and processes, could be regarded as one very important factor in a general spiritual awakening of collective human consciousness. Other factors that could be mentioned in this connection are the revolutionary paradigm shifts in the physical and biological sciences, the burgeoning of interest in Eastern philosophies and spiritual disciplines, and the growing awareness of the multi-cultural oneness of the human family brought about by the global communications networks.

Entheogenic substances in shamanistic cultures

In earlier writings, I emphasized the newness of psychedelic drugs and the unimaginable potentials to be realized by their constructive application. I viewed them as first products of a technology oriented toward the human spirit. I still appreciate the potential role of the new synthetic psychedelics in consciousness research, and perhaps consciousness evolution. However, my views have changed somewhat under the influence of the discoveries and writings of cultural anthropologists and ethnobotanists, who have pointed to the role of mind-altering and visionary botanicals in traditional cultures across the world. In such a worldview, closer to that of aboriginal cultures, humanity is seen as being in a relationship of co-consciousness, communication and cooperation with the animal kingdom, the plant kingdom and the mineral world. In such cultures, the ingestion of hallucinogenic plant preparations in order to obtain knowledge - for healing, for prophecy, for communication with spirits, for anticipation of danger, and for understanding the universe, appears as one of the oldest and most highly treasured traditions.

One cannot read the works of R. Gordon Wasson on the Mesoamerican mushroom cults, or the work of Richard E. Schultes on the profusion of hallucinogens in the Amazon region, or the cross-cultural studies of such authors as Michael Harner, Joan Halifax, Peter Furst, Wade Davis and Luis Eduardo Luna, or the cross-culturally oriented medical and psychiatric researchers such as Andrew Weil, Claudio Naranjo and Stanislav Grof, or more personal accounts such as the writings of Carlos Castaneda, or the McKenna brothers, or Bruce Lamb's biography of Manuel Cordova, without getting a strong sense of the pervasiveness of the quest for visions, insights and non-ordinary states of consciousness in the worldwide shamanic traditions. These studies demonstrate that psychoactive plants and fungi are used in many, though by no means all of the shamanic cultures that pursue such states. In the shamanistic cultures of the Northern hemispere, in America, Europe and Asia, the use of the drumming-journey method appears more widespread - possibly because there is a relative paucity of visionary hallucinogens in the temperate zones, as compared to the tropics.

Shamanic cultures all over the world know a wide variety of means for entering non-ordinary realities. Michael

Harner has pointed out that "auditory driving" with prolonged drumming is perhaps as equally a widespread technology for entering shamanic states as the use of hallucinogens. In some cultures, the rhythmic hyperventilation produced through certain kinds of chanting may be another form of altered state trigger. Animal spirits become guides and allies in shamanic initiation. Plant spirits can become "helpers" also, even when the plant is not taken internally by either doctor or patient. Tobacco smoke used as a purifier, as well as a support to prayer, is actually the most widely used psychoactive plant substance in indigenous and mestizo South American societies. In some traditions crystals are also used in ceremonies, in addition to plants, to focus energy for seeing and healing. There is attunement, through prayer and meditation, with deities and spirits of the land, the four directions, the elements, the Creator Spirit. The knowledge obtained from other states and other worlds is used to improve the way we live in this world. The use of hallucinogenic plants, when it occurs, is usually part of an integrated complex of interrelationships between nature, spirit and human consciousness.

Thus it seems to me that the lessons we are to learn from these consciousness-expanding plants in shamanism have to do not only with the recognition of other dimensions of the human psyche, but with a radically different worldview - a world view that has been maintained in the beliefs, practices and rituals of many indigenous shamanic cultures, and almost totally forgotten or suppressed by the materialist culture of the modern age. There is of course a certain delightful irony in the fact that it has taken a material substance to awaken the sleeping consciousness of so many of our contemporaries to the reality of non-material energies, forms and beings.

The potentials of entheogens in healing ritual practices

If we compare how Western medicine and psychotherapy have, so far, incorporated psychedelics into healing practice (really only on a very limited research basis), with shamanic healing ceremonies involving entheogenic plant substances, a perception of the importance of ritual is inescapable. The traditional shamanic ceremonial form involving hallucinogenic plants is a carefully structured experience, in which a small group of people come together with respectful, spiritual attitude to share a profound inner journey of healing and transformation, facilitated by these powerful catalysts. A "journey" is the preferred metaphor in shamanistic societies for what we call an "altered state of consciousness".

There are three significant differences between shamanic entheogenic ceremonies and the typical psychedelic psychotherapy. *One* is that the traditional shamanic rituals involve very little or no talking among the participants, except perhaps during a preparatory phase, or after the experience to clarify the teachings and visions received. The *second* is that singing, or the shaman's singing, is invariably considered essential to the success of the healing or divinatory process. Furthermore the singing typical in etheogenic rituals usually has a fairly rapid beat, similar to the rhythmic pulse in shamanic drumming journeys. Psychically, the rhythmic chanting, like the drum pulse, seems to give support for moving through the flow of visions, and minimize the likelihood of getting stuck in frightening or seductive experiences. The *third* distinctive feature of traditional ceremonies is that they are almost always done in darkness or low light, - which facilitates the emergence of visions. The exception is the peyote ceremony, done around a fire (though also at night); here participants may see visions as they stare into the fire.

I will briefly mention some of the variations on the traditional rituals involving hallucinogens. In the *peyote* ceremonies of the Native American Church, in North America, participants sit in a circle, in a tipi, on the ground, around a blazing central fire. The ceremony goes all night, and is conducted by a "roadman", with the assistance of a drummer, a firekeeper and a cedar-man (for purification). A staff and rattle are passed around and participants sing the peyote songs, which involve a rapid, rhythmic beat. The peyote ceremonies of the Huichol Indians of Northern Mexico also take place around a fire, with much singing and story-telling, after the long group pilgrimage to find the rare cactus.

The ceremonies of the *San Pedro* cactus, in the Andean regions, are sometimes also done around a fire, with singing; but sometimes the *curandero* sets up an altar, on which are placed different symbolic figurines and objects, representing the light and dark spirits which one is likely to encounter.

The mushroom ceremonies (*velada*) of the Mazatec Indians of Mexico, involve the participants sitting or lying in a very dark room, with only a small candle. The healer, who may be a woman or a man, sings almost uninterruptedly, throughout the night, weaving into her chants the names of Christian saints, her spirit allies and the spirits of the Earth, the elements, animals and plants, the sky, the waters and the fire.

Traditional Amazonian Indian or mestizo ceremonies with ayahuasca also involve a small group sitting in a circle, in semi-darkness, while the initiated healers sing the songs (*icaros*), through which the healing and/or diagnosis takes place. These songs also have a fairly rapid rhythmic pulse, which keeps the flow of the experience moving along. Shamanic "sucking" methods of extracting toxic psychic residues or sorcerous implants are sometimes used.

The ceremonies involving the root of the African *iboga* plant, used by the Bwiti cult in Gabon and Zaïre, involve an altar with ancestral and deity images, and people sitting on the floor with much chanting and some dancing. Often, there is a mirror in the assembly room, in which the initiates may "see" their ancestral spirits.

In comparing Western psychoactive-assisted psychotherapy with shamanic entheogenic healing rituals, we can see that the role of an experienced guide or therapist is equally central in both, and the importance of set (intention) and setting is implicitly recognized and articulated into the forms of the ritual. The underlying intention in both practices is healing and problem resolution. Therapeutic results can occur with both approaches, though the underlying paradigms of illness and treatment are completely different. The two elements in the shamanic traditions that pose the most direct and radical challenge to the accepted Western worldview are the existence of multiple worlds and of spirit beings - such conceptions are considered completely beyond the pale of both reason and science, though they are taken for granted in the worldview of traditional shamanistic societies.

It is worth mentioning that in the case of *ayahuasca*, there have grown in Brazil three distinct syncretic religious movements or churches, that incorporate the taking of ayahuasca into their religious ceremonies as the central sacrament. Here the intention of the ritual is not so much healing or therapeutic insight, as it is strengthening moral values and community bonds. The ceremonial forms here resemble much more the rituals of worship in a church, than they resemble either a psychotherapist's office, or a shamanic healing session.

There are also several different kinds of set-and-setting rituals using hallucinogens in the modern West, ranging from the casual, recreational "tripping" of a few friends to "rave" events of hundreds or even thousands, combining Ecstasy (MDMA) with the continuous rhythmic pulse of techno music. My own research has focussed on what might be called neo-shamanic medicine circles, which represent a kind of hybrid of the psychotherapeutic and traditional shamanic approaches. In the past forty years or so I have been a participant and observer in hundreds of such circle rituals, in both Europe and North America. Plant entheogens used in these circle rituals have included psilocybe mushrooms, ayahuasca, san pedro cactus, iboga and others. My interest has focussed on the nature of the psychospiritual transformation undergone by participants in such circle rituals.

In these hybrid therapeutic-shamanic circle rituals certain basic elements from traditional shamanic healing ceremonies are usually, though not always, kept intact:

- the structure of a circle, with participants either sitting or lying;
- an altar in the center of the circle, or a fire in the center if outside;
- presence of an experienced elder or guide, sometimes with assistants;
- preference for low light, or semi-darkness; sometimes eye-shades are used;
- use of music: drumming, rattling, singing or evocative recorded music;
- dedication of ritual space through invocation of spirits of four directions;
- cultivation of a respectful, spiritual attitude.

Experienced entheogenic explorers understand the importance of set and therefore devote considerable attention to clarifying their intentions with respect to healing and divination. They also understand the importance of setting and therefore devote considerable care to arranging a peaceful place and time, filled with natural beauty and free from outside distractions or interruptions.

Most of the participants in circles of this kind that I have observed were experienced in one or more psychospiritual practices, including shamanic drum journeying, Buddhist *vipassana* meditation, tantra yoga and holotropic breath-work and most have experienced and/or practiced various forms of psychotherapy and body-oriented therapy. The insights and learnings from these practices are woven by the participants into their work with the entheogenic medicines. Participants tend to confirm that the entheogenic plant medicines, when combined with meditative or therapeutic insight processes, function to amplify awareness and sensitize perception, particularly amplifying somatic, emotional and instinctual awareness.

Some variation of the *talking staff* or *singing staff* is often used in such ceremonies: with this practice, which seems to have originated among the Indians of the Pacific Northwest, and is also more generally now referred to as "council", only the person who has the circulating staff sings or speaks, and there is no discussion, questioning or interpretation (as there might be in the usual group psychotherapy formats). Some group sessions however involve minimal or no interaction between the participants during the time of the expanded state of consciousness.

In preparation for the circle ritual there is usually a sharing of intentions and purposes among the participants, as well as the practice of meditation, or sometimes solo time in nature, or expressive arts modalities, such as drawing, painting or journal work. After the circle ritual, sometimes the morning after, there is usually an integration practice of some kind, which may involve participants sharing something of the lessons learned and to be applied in their lives.

Concluding reflections

It appears incontrovertible that plant (and fungal) hallucinogens played some role, of unknown extent, in the healing and transformative traditions of shamanism. If we regard psychotherapy as the modern descendant of these traditions, then a similar, if limited, application of hallucinogens could be made in various aspects of psychotherapy. And this has in fact already occurred, as the various studies of psychedelics in alcoholism, terminal cancer, obsessional neurosis, depression and other conditions testify. It seems likely that these kinds of applications of psychedelics, as adjuncts to psychotherapy, will continue, - if not with LSD and other Schedule I drugs, then with other, newer, perhaps safer psychedelics.

What appears unlikely to me is that this kind of controlled psychiatric application will ever be enough to satisfy the inclinations and needs of those individuals who wish to explore psychedelics in their most ancient role, as tools for seeking visionary states and hidden forms of knowledge. The fact that the serious use of hallucinogens, outside of a psychiatric framework, continues despite severe social and legal sanctions, suggests that this is a kind of individual freedom that is not easy to abolish. It also suggests that there is a strong need, in certain people, to re-establish their connections with ancient traditions of knowledge, in which visionary states of consciousness and exploration of other realities, with or without hallucinogens, were the central concern.

It may be that such a path will always be pursued by only a limited number of individuals - much as the shamanic, alchemical and yogic initiations and practices were pursued by only a few individuals in each society. I find it a hopeful sign that some, however few, are willing to explore how to re-connect with these lost sources of knowledge, because, like many others, I feel that our materialist-technological society, with its fragmented world-view, has largely lost its way, and can ill afford to ignore any potential aids to greater knowledge of the human mind. The ecologically balanced and integrative framework of understanding that the ancient traditions preserved surely has much to offer us.

Furthermore, it is clear that the visions and insights of the individuals who pursue these paths are visions and insights for the present and the future, and not just of historical or anthropological interest. This has always been the pattern: the individual seeks a vision to understand his or her place, or destiny, as a member of the community. The knowledge derived from expanded states of consciousness has been, can be, and needs to be applied to the solution of the staggering problems that confront our species. This is why the discoveries of the mystical chemists and ethnobotanists have immense importance - for the understanding of our past, the awareness of our presence, and the safeguarding of our future.

Abstract

Rationale: Previous research suggests that classical psychedelic compounds can induce lasting changes in personality traits, attitudes and beliefs in both healthy subjects and patient populations.
Aim: Here we sought to investigate the effects of psilocybin on nature relatedness and libertarian-authoritarian political perspective in patients with treatment-resistant depression (TRD).
Methods: This open-label pilot study with a mixed-model design studied the effects of psilocybin on measures of nature relatedness and libertarian-authoritarian political perspective in patients with moderate to severe TRD (n=7) versus age-matched non-treated healthy control subjects (n=7). Psilocybin was administered in two oral dosing sessions (10 mg and 25 mg) 1 week apart. Main outcome measures were collected 1 week and 7-12 months after the second dosing session. Nature relatedness and libertarian-authoritarian political perspective were assessed using the

Nature Relatedness Scale (NR-6) and Political Perspective Questionnaire (PPQ-5), respectively.
Results: Nature relatedness significantly increased (*t*(6)=-4.242, *p*=0.003) and authoritarianism significantly decreased (*t*(6)=2.120, *p*=0.039) for the patients 1 week after the dosing sessions. At 7-12 months post-dosing, nature relatedness remained significantly increased (*t*(5)=-2.707, *p*=0.021) and authoritarianism remained decreased at trend level (*t*(5)=-1.811, *p*=0.065). No differences were found on either measure for the non-treated healthy control subjects.
Conclusions: This pilot study suggests that psilocybin with psychological support might produce lasting changes in attitudes and beliefs. Although it would be premature to infer causality from this small study, the possibility of drug-induced changes in belief systems seems sufficiently intriguing and timely to deserve further investigation.

Keywords
Psilocybin, nature relatedness, authoritarianism, depression, political perspective

Introduction

A growing body of evidence suggests that classical psychedelic compounds such as lysergic acid diethylamide (LSD) (Carhart-Harris *et al*., 2016b; Schmid and Liechti, 2017), psilocybin (Carhart-Harris *et al*., 2016a; Griffiths *et al*., 2016; Ross *et al*., 2016) and *N,N*-dimethyltryptamine (DMT) in ayahuasca (Osorio Fde *et al*., 2015) can promote enduring changes in personality traits, attitudes and beliefs - and similar effects have recently been reported for 3,4-methylenedioxy-methamphetamine (MDMA), which shares some properties with classical psychedelic compounds (Wagner *et al*., 2017) albeit with some important differences (Carhart-Harris and Nutt, 2017). Focusing more specifically on psilocybin, a single high dose of this naturally occurring compound was associated with enduring increases in trait openness, psychological wellbeing and life satisfaction in healthy volunteers 14 months later (Griffiths *et al*., 2008; MacLean *et al*., 2011). Psilocybin has also been shown to improve symptoms of addiction (Bogenschutz *et al*., 2015; Johnson *et al*., 2014), anxiety (Griffiths *et al*., 2016; Grob *et al*., 2011; Moreno *et al*., 2006; Ross *et al*., 2016) and depression (Carhart-Harris *et al*., 2016a; Griffiths *et al*., 2016; Ross *et al*., 2016) when administered in a psychologically supportive setting.

In the general population, psychedelic drug use is not associated with increased incidence of mental health problems (Johansen and Krebs, 2015; Krebs and Johansen, 2013), but is instead associated with lower rates of suicidality and psychological distress (Hendricks *et al*., 2015a, 2015b; Johansen and Krebs, 2015; Krebs and Johansen, 2013). Psychedelic drug users have also been shown to exhibit greater optimism (or reduced pessimism) than non-users (Grob *et al*., 1996) as well as increased concern for others, nature and the environment when compared with users of cannabis, amphetamine or heroin (Lerner and Lyvers, 2006). Experience with psychedelics has been found to positively affect one's sense of feeling part of nature rather than separate from it, leading to pro-environmental behavioural changes (Forstmann and Sagioglou, 2017). Nature relatedness, defined as the subjective sense of connection with the natural environment, is associated with lower levels of anxiety (Capaldi *et al*., 2014; Martyn and Brymer, 2014), and has been shown to promote psychological wellbeing at both the trait (Cervinka *et al*., 2012; Howell *et al*., 2011; Mayer and Frantz, 2004; Nisbet *et al*., 2011) and state (Mayer *et al*., 2008; Nisbet and Zelenski, 2011) level. Furthermore, interacting with the natural environment has been shown to improve mood and cognitive functioning in patients with major depressive disorder (MDD) (Berman *et al*., 2012), and visits to outdoor green spaces of 30 min or more per week has been predicted to reduce the population prevalence of depression by up to 7% (Shanahan *et al*., 2016). Taken together, these findings indicate that psychedelics can promote enduring changes in personality traits, attitudes and beliefs.

A recent correlational study of ours found that lifetime psychedelic drug use in the general population positively predicted nature relatedness and negatively predicted authoritarian political views, in a manner that appeared to be mediated by acute and temporary 'ego-dissolution' (Nour *et al*., 2017). Moreover, a recent pilot study of ours found rapid and enduring reductions in depressive symptoms in a treatment-resistant depression (TRD) sample after psychologically supported psilocybin therapy (Carhart-Harris *et al*., 2018a). As part of this project, the present research sought to address potential changes in nature relatedness and political perspective in this sample of TRD patients before versus after psilocybin treatment. Measures were collected at screening, 1 week and 7-12 months post-dosing. To demonstrate robustness to order confounds, we also collected data from an age-matched but non-treated healthy control group, tested over an equivalent period.

Methods

Ethical approvals

This study received a favourable opinion from NRES London-West London, was sponsored by Imperial College London, and was carried out in accordance with Good Clinical Practice Guidelines. The National Institute for Health Research/Wellcome Trust Imperial Clinical Research Facility (ICRF) provided site-specific approval and the Medicines and Healthcare products Regulatory Agency (MHRA) reviewed and approved this research. All patients provided written informed consent.

Study design and participants

This open-label pilot study with a mixed-model design compared the effects of psilocybin on nature relatedness and libertarian-authoritarian political perspective in patients with TRD versus healthy control subjects. The findings presented here are part of a larger open-label pilot study of psilocybin in TRD, the results of which have been reported elsewhere (Carhart-Harris *et al.*, 2016a, 2017). The study participants (*n*=14) and research team were not masked to treatment assignment. All TRD patients (*n*=7) were administered psilocybin in two dosing sessions: an initial safety dose (10 mg) and a subsequent treatment dose (25 mg) 1 week later. The control subjects (*n*=7) were not administered psilocybin and were primarily included to examine test-retest data on the relevant primary measures.

General practitioners were provided with recruitment information via the North West London Clinical Research Network and were asked to identify potential patients with TRD. TRD patients residing in the UK were also able to self-refer to the study. In most cases, it was the TRD patients that initiated contact with the research team. After initiating contact, patients were given a study information sheet and were initially screened via a telephone call with the research team's lead psychiatrist to determine eligibility for the study. Each patient's general practitioner or psychiatrist provided written confirmation and documentation of the patient's diagnosis and mental health background.

The inclusion criteria were (a) MDD of a moderate to severe degree (16+ on the 21-item Hamilton Depression Rating scale [HAM-D]), and (b) no improvement despite two adequate courses of antidepressant treatment of different pharmacological classes lasting at least six weeks within the current depressive episode. The exclusion criteria were (a) current or previously diagnosed psychotic disorder, (b) first-degree relative with a diagnosed psychotic disorder, (c) medically significant condition rendering unsuitability for the study, (d) history of serious suicide attempts (requiring hospitalisation), (e) previous manic episode, (f) blood or needle phobia, (g) positive pregnancy test at screening or during the study, and (h) current drug or alcohol dependence.

Physically and mentally healthy age-matched control subjects were recruited via word of mouth and were subject to the same exclusion criteria outlined above. Informed consent was obtained from all of the study participants, including the controls.

Drug

Psilocybin was obtained from THC Pharm GmbH (Frankfurt, Germany) and formulated by Guy's and St Thomas' Hospitals' Pharmacy Manufacturing Unit (London, UK). Home Office approvals for storing and dispensing Schedule One drugs were obtained.

Procedures and dosing sessions

Screening procedures typically lasted 4 h and consisted of psychiatric and physical health assessments. All patients provided written informed consent. Clinicians carried out a Mini-International Neuropsychiatric Interview (Sheehan *et al.*, 1998) and assessed depression severity using the HAM-D (Hamilton, 1960) and Montgomery-Åsberg Depression Rating Scale (MADRS) (Montgomery and Asberg, 1979) in patient participants. Physical assessments included an electrocardiogram, routine blood tests, blood pressure and heart rate tests, and a physical examination. Eligible TRD patients were allocated two psychiatrists for support throughout the study.

All patients enrolled in the study attended a pre-dosing preparatory session with the allocated psychiatrists on the next visit. Psychological preparation consisted of discussing the effects of psilocybin and simulating aspects of the dosing session to make patients aware of what to expect. Patients also shared their personal history and thoughts on the origins of their depression. This session helped to build rapport and trust between the patient and their allocated psychiatrists, thus minimising the risk of adverse reactions to psilocybin (Metzner *et al.*, 1965).

All patients attended two dosing sessions separated by 1 week at the ICRF. A close friend or relative accompanied each patient to and from the ICRF and return transport was arranged before the dosing sessions took place. A urine sample for drugs of abuse (and pregnancy where applicable), breathalyser test for alcohol use and vital signs measurements were collected before each dosing session. Patients were then taken to a decorated dosing room with dim lighting and music where they were invited to lie down and relax. The allocated psychiatrists remained at either side of the bed and adopted a non-directive, supportive approach. Patients were supervised at all times and the psychiatrists checked how they were feeling at approximately 1 h intervals, and assessed them for discharge approximately 6 h after drug administration.

Outcome measures

To assess political views on the dimension of libertarianism to authoritarianism, a recently validated (Nour *et al.*, 2017) subset of questions (five items) from the Libertarian-Authoritarian Questionnaire (Evans *et al.*, 1996) were used as a short version and termed the Political Perspective Questionnaire (PPQ-5) (Nour *et al.*, 2017). The validated 6-item Nature Relatedness Scale (NR-6) (Nisbet and Zelenski, 2013) was used to measure the subjective sense of connectedness to nature. Self-rated depressive symptoms were measured at baseline and two followup time points (1 week and 7-12 months) in all study participants using the Quick Inventory of Depressive Symptoms (QIDS) (Rush *et al.*, 2003). The above measures were assessed at baseline and then again at the 1 week and 7-12-months follow-ups for all study participants.

Statistical analysis

All statistical analyses were performed using SPSS version 23.0 (IBM Corp., Armonk, NY, USA). Within-group comparisons were performed using one-tailed paired *t*-tests for parametric data and Wilcoxon signed ranks tests for non-parametric data. Between-group comparisons were performed using two-tailed independent *t*-tests for parametric data and Mann-Whitney *U* tests for non-parametric data. We provide 95% CIs around the mean differences. Effect sizes were calculated using the Hedges' *g* formula due to the small sample size in this study

Results

No serious adverse events occurred as a result of the psilocybin administration, and the acute drug effects were well tolerated by all patients (see Carhart-Harris *et al*. (2016a, 2017a) for more information).

Demographics

Of the total 14 participants who took part in this study, the majority were Caucasian (78.6%) and men (64.3%) with a post-secondary level of education (85.7%). In the patient sample (*n*=7), baseline HAM-D scores ranged from 24 to 36 (*M*=28.6, *SD*=3.7) and the MADRS scores from 28 to 40 (*M*=35.9, *SD*=5); thus, all patients recruited were diagnosed with TRD of at least moderate severity, with most meeting criteria for severe depression. Control subjects were not clinically assessed because they were deemed physically and mentally healthy. Self-reported depressive symptoms (QIDS) were collected for all study participants. Table 1 outlines participant demographic details and depressive scores at baseline.

Table 1. Study participant demographics and baseline depression scores.

Characteristic	Control subjects (*n*=7)	TRD patients (*n*=7)	All participants (*n*=14)	*p*-value
Gender (% male)	29%	100%	64.3%	0.005[a]
Age in years (mean, SEM)	43.3 (6.8)	48.3 (4.5)	45.8 (3.9)	0.550[b]
Ethnicity (%)				0.213[a]
White	71.4%	85.7%	78.6%	
Black	0%	14.3%	7.1%	
Asian	28.6%	0%	14.3%	
Education (%)				1.000[a]

Nature relatedness

Patients showed a significant increase in nature relatedness scores 1 week after psilocybin treatment (*M*=4.14, *SD*=0.75) compared with baseline (*M*=3.67, *SD*=1.00); *t*(6)=-4.242, *p*=0.003, 95% CI [-0.75, 0.2]. The Hedges' g value (*g*=2.5) for this contrast was very large, and the significant change was sustained at the 7-12-month follow-up time-point (*M*=4.12, *SD*=0.60; *t*(5)=-2.707, *p*=0.021, 95% CI [-1.15, -0.03]; *g*=1.2). Non-treated control subjects showed no difference between screening (*M*=4.02, *SD*=0.79) and the first (*M*=4.02, *SD*=0.94; *t*(6)=0.008, *p*=0.994, 95% CI [-0.46, 0.46]) or second (*M*=4.05, *SD*=0.62; *t*(5)=-1.228, *p*=0.274, 95% CI [-0.60, 0.21]) follow-ups. No significant between-groups differences were found at baseline (*p*=0.471) or the first (*p*=0.799) and second (*p*=0.861) follow-ups. These results suggest that psilocybin therapy increases the subjective sense of connectedness to nature 1 week after treatment, and that these effects are sustained for at least 7-12 months (Figure 1(a)).

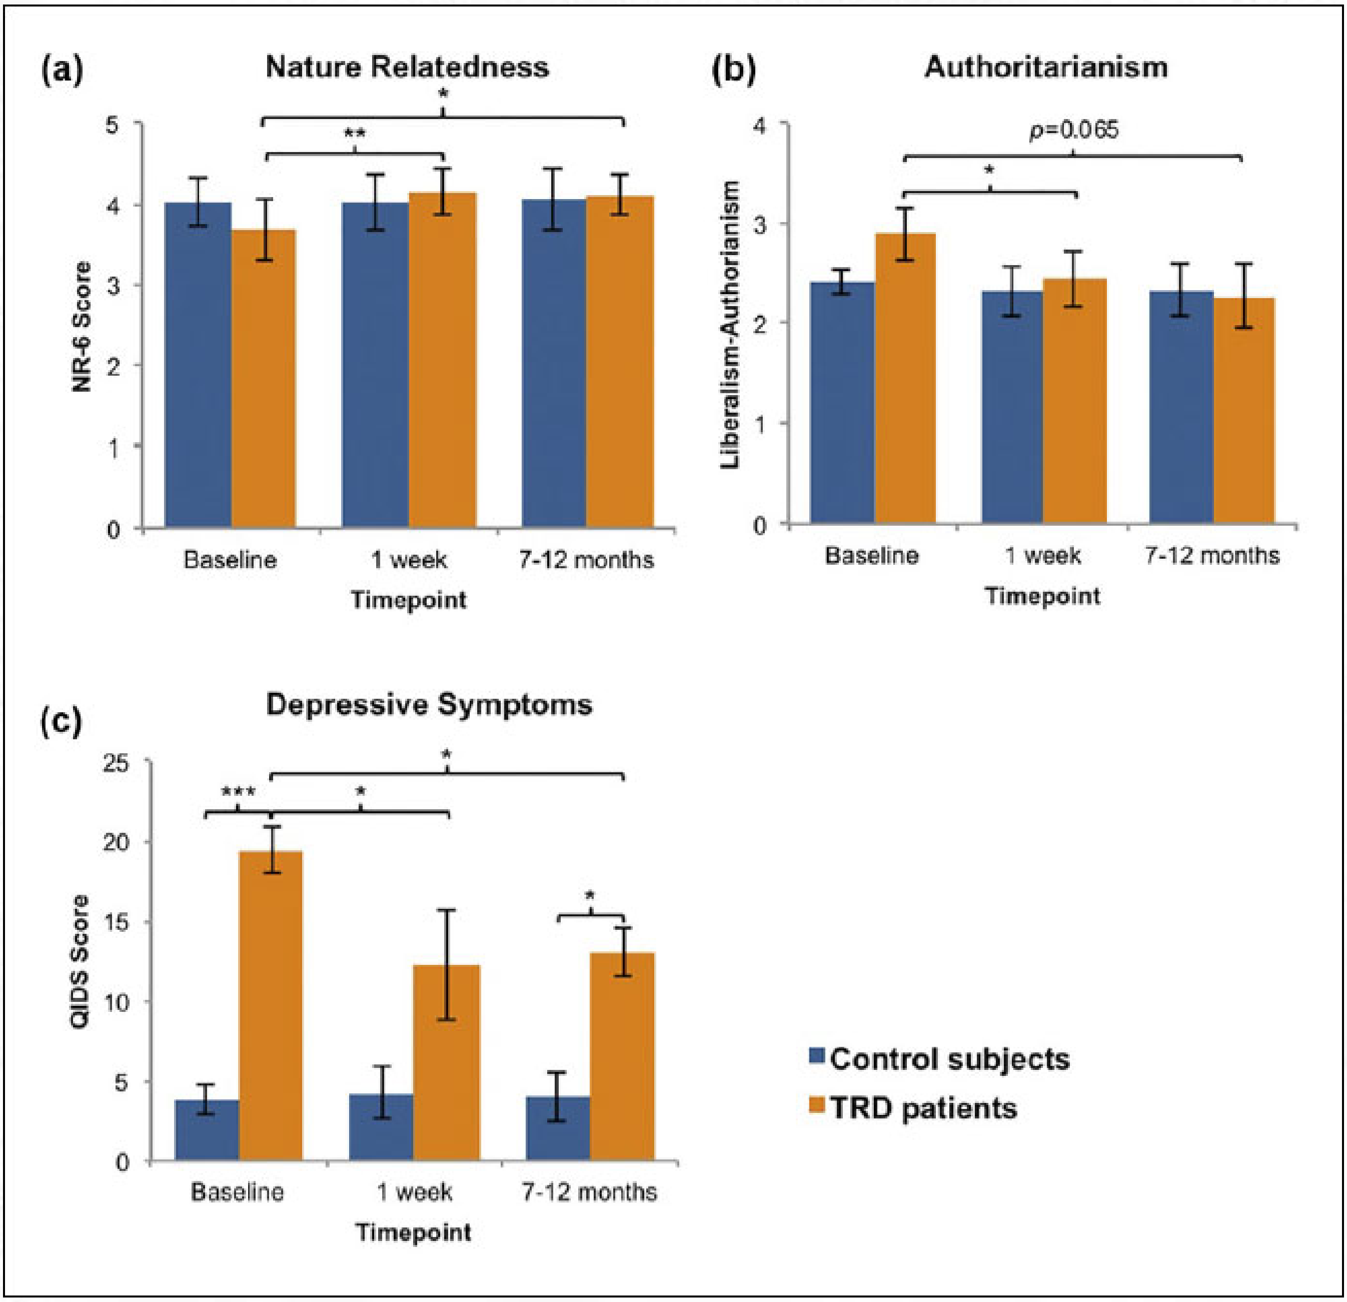

Figure 1. (a) Nature relatedness. Patients reported being significantly more connected to nature 1 week ($t(6)=-4.242$, $p=0.003$) and 7-12 months ($t(5)=-2.707$, $p=0.021$) after psilocybin treatment compared with baseline. No significant difference was found for the controls at the first ($t(6)=0.008$, $p=0.994$) or second follow-ups ($t(5)=-1.228$, $p=0.274$). (b) Political perspective. Patients were significantly less authoritarian 1 week after psilocybin treatment ($t(6)=2.120$, $p=0.039$) and a trend-level decrease was found at 7-12 months ($t(5)=-1.811$, $p=0.065$) compared with baseline. No significant differences were found for the controls at the first ($t(6)=0.642$, $p=0.544$) or second follow-up ($t(5)=0.515$, $p=0.629$). (c) Depressive symptoms. Patients had significantly more depressive symptoms than controls at baseline ($U=0.0E0$, $p=0.001$). One week after psilocybin treatment, depressive symptoms were significantly reduced to levels more comparable with controls ($Z=-2.040$, $p=0.025$) as no significant between-groups differences were found ($U=10.000$, $p=0.062$). The patients' depressive symptoms remained significantly reduced at the 7-12-months follow-up ($Z=-1.782$, $p=0.038$); however, a between-groups difference was found ($U=3.500$, $p=0.020$). No significant differences were found for the control subjects at the first ($Z=-0.422$, $p=0.673$) or second ($Z=-0.137$, $p=0.891$) follow-ups compared with baseline. Data expressed as mean ± SEM [$p<0.05$*; $p\leq0.01$**; $p\leq0.001$***].

Political perspective

Patients showed a significant decrease in authoritarian political perspective 1 week after psilocybin treatment ($M=2.43$, $SD=0.73$) relative to baseline ($M=2.89$, $SD=0.72$); $t(6)=2.120$, $p=0.039$; 95% CI [-0.07, 0.99]. The Hedges' g value ($g=0.8$) was found to meet the conventional criterion for a large effect size. Decreases in authoritarianism were still evident 7-12 months post-dosing ($M=2.27$, $SD=0.68$), and although this trend-level effect no longer reached conventions for statistical significance ($t(5)=-1.811$, $p=0.065$, 95% CI [-0.25, 1.46]), the relevant Hedges' g value ($g=0.7$) met convention for a medium-to-large effect size, suggesting that this study was underpowered to detect a statistically significant result on this particular measure. Nontreated control subjects showed no change in authoritarianism between screening ($M=2.40$, $SD=0.35$) and the first

(*M*=2.31, *SD*=0.66; *t*(6)=0.642, *p*=0.544) or second (*M*=2.33, *SD*=0.78; *t*(5)=0.515, *p*=0.629) follow-ups. No significant between-groups differences were found at baseline (*p*=0.132) or the first (*p*=0.755) or second (*p*=0.877) follow-ups. These results suggest that psilocybin therapy may persistently decrease authoritarian attitudes post-treatment with psilocybin, but that further research is required to test the robustness of this relationship (Figure 1(b)).

Depressive symptoms

Baseline depressive symptoms (QIDS ratings) were significantly higher in patients (*M*=19.43, *SD*=4.04) than controls (*M*=3.86, *SD*=2.41); *U*=0.0E0, *p*=0.001 (Figure 1(c)). Further, the Hedges' g effect size value for this contrast (*g*=4.7) was, by convention, exceptionally high, confirming our assumption that the patients had far higher (baseline) self-reported depressive symptoms than the controls.

Therapeutic outcomes for the full sample are given in previous publications (Carhart-Harris *et al*., 2016a, 2018a, 2017). In the sample reported in this paper, patients showed a significant decrease in QIDS scores 1 week after the psilocybin sessions (*M*=12.29, *SD*=9.18) compared with baseline (*M*=19.43, *SD*=4.04); *Z*=-2.04, *p*=0.025 (Figure 1(c)). Further, the Hedges' g value for this contrast (g=1.3) was, again, large by convention. There was no significant difference found in the controls' baseline (*M*=3.86, *SD*=2.41) versus 1-week follow-up QIDS scores (*M*=4.29, *SD*=4.35; *Z*=-0.422, *p*=0.673). These results confirm that depressive symptoms were significantly reduced for the patients 1 week after psilocybin treatment, but did not change over an equivalent period for the non-treated control subjects.

The patients' 1 week post-treatment QIDS scores (*M*=12.29, *SD*=9.18) did not differ significantly from the controls' follow-up values (*M*=4.29, *SD*=4.35; *U*=10.000, *p*=0.062), implying that the patients' depressive symptoms were reduced to levels comparable with a healthy population at the 1-week post-treatment time-point (Figure 1(c)).

The patients' QIDS scores remained significantly decreased 7-12 months after psilocybin treatment (*M*=13.00, *SD*=6.39) compared with baseline (*M*=19.43, *SD*=4.04); *Z*=-1.782, *p*=0.038. Moreover, the Hedges' g value (*g*=0.7) for this contrast was 'medium-to-large'. There was no significant difference found in the controls' baseline (*M*=3.86, *SD*=2.41) versus 7-12-month follow-up QIDS scores (*M*=4.00, *SD*=3.58); *Z*=-0.137, *p*=0.891 (Figure 1(c)). These results confirm that the patients' significant reductions in depressive symptoms were sustained for 7-12 months after psilocybin treatment, and did not change over an equivalent period for the non-treated control subjects.

Discussion

The present study sought to investigate the effects of psilocybin with psychological support on nature relatedness and authoritarianism in patients with TRD. Patients reported a greater connection with nature 1 week after treatment. This increase in nature relatedness was sustained at the 7-12-months follow-up. One week post-treatment a significant decrease in authoritarianism was also observed, and at the 7-12-month follow-up the decrease was at trend level. No significant differences in nature relatedness, authoritarianism or depressive symptoms were found in an age and education-matched group of control subjects measured over an equivalent time period, thus supporting the inference that the changes were *not* due to order effects. Taken together, these findings indicate that the psychologically supportive administration of psilocybin might induce sustained changes in attitudes and beliefs, including feeling closer to nature and less allied to authoritarian views.

The reduction of depressive symptoms following psilocybin treatment found here is consistent with previous studies demonstrating the therapeutic potential of psychedelic compounds (Carhart-Harris and Goodwin, 2017). Long-term improvements in psychological wellbeing (Griffiths *et al*., 2008) and trait openness and optimism (Carhart-Harris *et al*., 2016b; MacLean *et al*., 2011; Schmid and Liechti, 2017) have been observed in healthy volunteers following a single exposure to a psychedelic drug. A single dose of psilocybin has also been shown to induce enduring reductions in anxiety and depression as well as increases in quality of life, life meaning, and optimism in patients with anxiety reactive to advanced-stage cancer (Griffiths *et al*., 2016; Grob *et al*., 2011; Ross *et al*., 2016). Furthermore, rapid and sustained antidepressant effects were found in patients with recurrent MDD that were treated with a single dose of the plant-based psychedelic brew, ayahuasca (Osorio Fde *et al.*, 2015).

Evidence suggests that greater nature relatedness is associated with lower anxiety (Martyn and Brymer, 2014) and greater personal wellbeing (Capaldi *et al.*, 2014; Cervinka *et al.*, 2012; Howell *et al.*, 2011; Mayer and Frantz, 2004; Mayer *et al.*, 2008; Nisbet and Zelenski, 2011; Nisbet *et al.*, 2011; Zelenski and Nisbet, 2014), and that exposure to awe-inspiring nature may increase pro-social behaviour (Piff *et al.*, 2015) - perhaps through a related mechanism of seeing oneself as small in relation to the vastness of nature. Here, we show that the TRD patients felt more connected to nature up to 7-12 months after psilocybin treatment. This is consistent with a previous study in healthy participants in which 38% of the sample reported enduring positive changes in their relationship to nature and the environment 8-16 months post-psilocybin (Studerus *et al.*, 2011). Psychedelic use in a large sample of web-survey respondents was found to positively predict nature relatedness (Nour *et al.*, 2017); moreover, as with nature-inspiring experiences of awe (Piff *et al.*, 2015), this relationship was strongest in people who experienced the greatest ego-dissolution during their most intense psychedelic experience (Nour *et al.*, 2017).

Psychedelic users have been found to rate themselves as more concerned with the environment than users of other illicit substances (Lerner and Lyvers, 2006; Nour *et al.*, 2017). Interacting with nature has been shown to have cognitive and affective benefits in healthy individuals (Berman *et al.*, 2008) and patients with MDD (Berman *et al.*, 2012). Although we found no correlation between the changes in nature relatedness or authoritarianism and changes in depression in the patients, this may simply have been due to the small sample size (*n*=7), or it is possible that a measure of mental wellbeing may have been more sensitive to such a relationship than the presently used measure of depression. There is, however, evidence to suggest that nature exposure decreases rumination as well as activity in brain regions implicated in depression (Hamilton *et al.*, 2015), namely the subgenual prefrontal cortex (sgPFC) and regions of the default mode network (DMN) (Bratman *et al.*, 2015). Interestingly, the administration of psilocybin has also been shown to acutely decrease sgPFC and DMN blood flow and within-network functional integrity (Carhart-Harris *et al.*, 2012; Hamilton *et al.*, 2015) and to increase global connectivity in the brain (Petri *et al.*, 2014; Roseman *et al.*, 2016). Further work is required to test the hypotheses that a renewed sense of 'connectedness', including feeling connected to nature, is a key factor determining therapeutic outcomes in psychedelic therapy (Carhart-Harris *et al.*, 2018b; Watts *et al.*, 2017b) and to better elucidate its basis in the brain. A working hypothesis is that increased global connectivity in the brain and its relationship to ego-dissolution (Tagliazucchi *et al.*, 2016) and associated 'connectedness' (Watts *et al.*, 2017b) is a key mediating factor (Carhart-Harris *et al.*, 2018b).

Psychedelic drug use in the 1960s and 1970s was strongly associated with anti-establishment and egalitarian counter-culture movements (Nichols, 2016), yet very little controlled research has investigated the link between psychedelic use and political perspectives. Here we show for the first time, in a controlled study, lasting changes in political values after exposure to a psychedelic drug. This is in line with early research showing that recreational LSD users score higher on attitudes of 'personal liberty' and 'foreign policy liberalism' than control subjects (McGlothlin and Arnold, 1971). Psychedelic users have also been shown to score higher on 'concern for others' and place lower value on 'financial prosperity' than non-users of illicit substances as well as users of amphetamine, cannabis or heroin (Lerner and Lyvers, 2006). Given that psychedelics act through the serotonin system, it is interesting that serotonin has been implicated in the assessment of harm in moral decision-making, altruistic punishment and fairness (Crockett *et al.*, 2008, 2010, 2013; Story *et al.*, 2015). Moreover, psychedelics have been shown to increase trait openness (Carhart-Harris *et al.*, 2016b; Griffiths *et al.*, 2008; MacLean *et al.*, 2011), and a substantial body of evidence demonstrates a positive association between openness and liberalism within individuals (Carney *et al.*, 2008; Nour *et al.*, 2017; Sibley *et al.*, 2012; Xu *et al.*, 2013). Relatedly, the role of the serotonin 2A receptor, the key site of action of psychedelics, in mediating 'conversion-type' or 'quantum change' (Miller, 2004) experiences has recently been discussed (Carhart-Harris and Nutt, 2017).

There are a number of important limitations to this study that must be considered when interpreting the results. The study formed part of an open-label clinical trial with a small sample size. The sample was smaller still for the NR-6 and PPQ-5, as these measures were introduced late in the trial due to inspiration from a separate project of ours (Nour *et al.*, 2017). Also, although we recruited a control group to examine test-retest reliability on these measures, the controls were healthy subjects and were not exposed to the same treatment procedures. Critically, since treatment with psilocybin involved more than just drug administration (e.g.

psychological support before and after the psilocybin dosing sessions), it is quite possible that drug-unrelated factors contributed to the changes in NR-6 and PPQ-5 scores observed here. The caring therapeutic model may have been one such factor. A large double-blind randomised control trial, ideally with an active control condition (to try and maintain the study blind), is required to more rigorously test the possible causal association between psilocybin and changes in nature relatedness and political perspective reported here. It would be hasty, therefore, to attempt any strong claims about a causal influence due specifically to psilocybin at this stage, and we should also be aware of anomalies in the relationship between psychedelic use and left-wing politics (Henrik, 2017); however, intriguing questions relating to psychedelics and political/philosophical perspectives remain.

A further limitation concerns the gender matching of control subjects and TRD patients; all TRD patients were male, whereas there were more females (71%) than males (29%) in the control condition. Thus, our findings in the TRD group cannot necessarily be extrapolated to females and the possibility of a gender effect cannot be discounted, and neither can we directly extrapolate the present findings to non-depressed populations.

The specificity of our main results also requires careful consideration. The question remains to be addressed whether the reported changes in nature relatedness and authoritarianism observed here post-treatment with psilocybin were selective for these outcomes, or rather an epiphenomenon of the treatment's core effects on depressive symptoms. The question of causality is of central relevance here, and only further research can elucidate this. In this context, we would like to propose that there is a common mediating factor at play, driving both the improvements in mental health and changes in belief systems seen here - as well as elsewhere with psilocybin and other psychedelics (Carhart-Harris *et al.*, 2016b; Hendricks *et al.*, 2015b; Krebs and Johansen, 2013; MacLean *et al.*, 2011). Such a common factor could be seen as a mental health equivalent of the general intelligence factor (e.g. Spearman's *g*) in cognitive science (Spearman, 1987; Spiegelman, 2010). More specifically, in line with a recent commentary from our team (Carhart-Harris *et al.*, 2018b) we propose that *connectedness* is this factor (see Carhart-Harris *et al.* (2018b); Watts *et al.* (2017b)), and that psychedelics positively and potently modulate this.

Connectedness is a construct in need of development, but related concepts can be found in the literature (Alexander, 2010). In brief, connectedness can be defined as a sense of feeling connected to one's self (i.e. a sense of feeling emotionally and somatically integrated and at peace) as well as others (e.g. one's partner, family, friends, colleagues and community) and the world more generally (e.g. feeling connected to nature and a guiding ethical and/or philosophical principle), as described in our recent work (Carhart-Harris *et al.*, 2018b; Watts *et al.*, 2017b). Thus, a remediating effect on feelings of disconnectedness, characteristic of a broad swathe of mental illness (Alexander, 2010), may underlie both the improvements in depressive symptoms and the relevant changes in political perspective reported here.

What of the association between mental health and political perspective? There is some support for a link between lower authoritarianism and better mental health (Amodio *et al.*, 2007; Hirsh *et al.*, 2010; Jost *et al.*, 2003), although there are also some contradictory findings (Verhulst *et al.*, 2016; Vigil, 2010). The idea that drugs, including legal ones such as alcohol (Nour *et al.*, 2016) and caffeine (Carpenter, 2015), and medications such as stimulants (Ohler and Whiteside, 2017) and selective serotonin reuptake inhibitors (Kramer, 1997) can modulate belief systems, including political perspective, is relatively new - but one that may be fundamentally important, with potentially profound implications. If, for example, it was found that excessive alcohol use promotes a detachment from nature (Nour *et al.*, 2016), chronic stimulant use promotes an aggressive industriousness and hubris - and potential for paranoia (Ohler and Whiteside, 2017) - and psychedelic experiences promote a generalised sense of connectedness (Carhart-Harris *et al.*, 2018b; Watts *et al.*, 2017b), including greater altruism (Forstmann and Sagioglou, 2017; Schmid and Liechti, 2017), what implications would this have for societies and their policies on such drugs? This and related topics may be seen as part of a new branch of political science, focused on the psychology and neurobiology of political perspective (Amodio *et al.*, 2007; Everett *et al.*, 2015; Haidt, 2013; Kanai *et al.*, 2011; Kaplan *et al.*, 2016; Nash *et al.*, 2017).

Finally, we are keen to avoid a value judgement about the political changes that may (or may not) be attributable to psychedelic use. For some, ecological considerations (e.g. captured by nature relatedness) may be assigned the greatest importance (Lovelock and Hudson, 2016), particularly when considering the scale and seriousness of the problem posed by climate change, for example (Prüss-Ustün *et al.*, 2016), whereas others may recognise 'order' (e.g. captured in part by our authoritarianism scale) as an essential and functional counterweight to lawlessness (Bejan, 2017; Haidt, 2013). Testing whether psychedelic use is 'beneficial for society' would be a complex project, not least because opinions will differ on how to define 'beneficial' (although see Harris (2010) for a thought-provoking discussion on this matter). Even so, exploring the potential of psychedelics to moderate extremist views, and/or facilitate reconciliation, might be worth exploring, given the present results and wider supporting literature (Amodio *et al*., 2007; Carhart-Harris *et al*., 2018b; Hirsh *et al*., 2010; Jost *et al*., 2003; Watts *et al*., 2017a).

In conclusion, this study sought to investigate the effects of psilocybin with psychological support on nature relatedness and authoritarian attitudes in patients with TRD. With significant caveats clearly highlighted, our findings tentatively raise the possibility that given in this way, psilocybin may produce sustained changes in outlook and political perspective, here in the direction of increased nature relatedness and decreased authoritarianism. These findings motivate further controlled studies to better determine the causality, reliability, specificity and durability of this relationship, as well as potential applications.

> Before I enjoyed nature, now I feel part of it. Before I was looking at it as a thing, like TV or a painting... [But now I see] there's no separation or distinction, you *are* it. (*Patient from this trial*)

Abstract

Older adulthood can be characterized by various cognitive and affective changes. In general, older adults show declines in creativity and executive functioning. They also score lower in openness to experience, empathy, and many suffer from a paucity of meaningful experiences. Further, depression, pessimism, and suicide can be major concerns for this population. Although currently there are few interventions that can effectively address these changes, recent findings from psychedelic science suggest myriad parallels between the effects of these drugs and the cognitive/affective shifts seen in older adulthood. Studies have shown that psychedelics are associated with enhanced creativity and executive functioning. They can also lead to increases in openness and empathy, and induce personally meaningful experiences. Lastly, psychedelics' efficacy for treating mood disorders and their role in palliative care are rapidly growing areas of scientific research. In this article, we analyze findings from contemporary psychedelic studies and integrate them with research on cognitive/affective changes in older adulthood to assess whether these drugs have potential to be incorporated into older adult research. We also assess the intuitive follow-up questions of potential mechanisms of action and safety concerns. Findings indicate that psychedelics have effects on a number of cognitive/affective processes that are altered in older adulthood, and are relatively safe when used with professional preparation and supervision. Increased neuroplasticity, neurogenesis, connectedness, and mystical experiences have been argued to underlie cognitive/affective changes. However, further research is needed to overcome current experimental limitations such as generalizability, unstandardized dosages, inadequate controls, and self-selection/experimenter biases.

Keywords Psychedelics, Cognition, Affect, Aging, Well-being

Introduction

A number of cognitive and affective changes have been documented in older adulthood, which is typically conceptualized as beginning in one's 60s (Salthouse 2009). These changes can include declines in creativity and generating novel ideas (Price and Tinker 2014), impaired executive functioning (Baudouin *et al*. 2019), decreased openness to experience (Donnellan and Lucas 2008), and decreased empathy (Grühn *et al*. 2008). Further, although depression scores generally drop after early adulthood, late-life depression is one of the most common causes of emotional suffering in older adults (Blazer 2003; Wang and Blazer 2015), and the elderly have higher rates of suicide than younger adults (De Leo and Meneghel 2001; Kumar *et al*. 2015). These changes in negative affect may be due in part to a lack of meaningful experiences: Baum (1988) found that when elderly persons were asked to recount their most meaningful life experiences, none of the 50 participants reported an event after the age of 40. Lastly, the number of neurons in the brain decreases in older age as neurons that die off are not replaced as efficiently (Galvan and Jin 2007). Because neurogenesis is thought to play a major role in age-related cognitive and affective deficits, interventions which stimulate neurogenesis may build-up a cognitive reserve which could help reduce the intellectual and emotional burdens in late-life (Xu *et al*. 2015).

This is not to say that aging is inherently negative as many older adults experience high life satisfaction and emotional stability (Charles and Carstensen 2010; Scheibe and Carstensen 2010). Yet, risk factors for cognitive and affective decline can have a cumulative effect across individuals' lifespans ultimately leading to impairment (Camacho *et al*. 1993; Zeki Al Hazzouri *et al*. 2014). Addressing these risk factors can stave off cognitive decline (Mossello *et al*. 2008) and identifying holistic treatments which target multiple risk factors could facilitate healthy aging (Cesari *et al*. 2013). Thus, while older adults show changes in cognition and affect at the group level, many variables can exert compensatory effects on individual trajectories (Smith 2016).

Psychedelic drugs such as lysergic acid diethylamide-25 (LSD), psilocybin, and ayahuasca have been shown to induce alterations in cognition and affect that run counter to the changes seen in older adulthood. Research into psychedelic drugs blossomed in the mid-twentieth century but was put to a halt in the late 1960s as the War on Drugs emerged (Aday *et al*. 2019). However, the last 10-15 years has seen a renaissance of psychedelic research, and their public stigma seems to be waning as evidenced by recent positive pieces in mainstream media outlets (e.g., the *New York Times* Carroll 2017; *Wall Street Journal* Pollan 2018; *Business Insider* Brodwin 2018) and successful decriminalization efforts in parts of the USA (Aday *et al*. 2018, A watershed year for psychedelic science, unpublished). There are many parallels between the findings from these new studies and psychological changes in older adulthood. First, psychedelics have been shown to increase divergent (Kuypers *et al*. 2016) and convergent creativity (Uthaug *et al*. 2018). They can also lead to long-lasting increases in the personality trait of openness (MacLean *et al*. 2011) as well as increasing empathy (Pokorny *et al*. 2017). Psychedelic-assisted psychotherapy has been shown to have promising effects on depression (Griffiths *et al*. 2016; Ross *et al*. 2016). Relatedly, psychedelic use is associated with decreased psychological distress and suicidality (Hendricks *et al*. 2015). Psychedelics may also address the lack of meaningful experiences in older adulthood: in one study, two thirds of participants reported their psychedelic session as being one of the top five most meaningful experiences of their life (Griffiths *et al*. 2006). Their role in palliative care is also a rapidly growing area of study (Shelton and Hendricks 2016). Lastly, there is emerging evidence in animal models that psychedelics can stimulate neurogenesis (Catlow *et al*. 2016; Lima da Cruz *et al*. 2018; Morales-García *et al*. 2017) and neuroplasticity (Ly *et al*. 2018), which may be key mechanisms facilitating improvements. Altogether, the reviewed literature suggests many parallels between cognitive/affective changes in older adulthood and the effects of psychedelic drugs. In this paper, we analyze recent findings in psychedelic research and synthesize them with studies on cognitive and affective changes in late-life to determine whether these substances have potential to be incorporated into older adult research.

Cognitive Parallels

Relative to younger individuals, older adults suffer deficits in cognition in areas such as memory and attention (Mok *et al*. 2016). Older age can also be associated with declines in creativity and executive functioning, and these changes in cognition may impair one's quality of life (Baudouin *et al*. 2019). There is growing evidence that psychedelic drug use is associated with improved creativity and executive functioning, suggesting that these drugs may have potential cognitive benefits for older adults.

Anecdotal reports about psychedelics' potential for improving creativity date back to the first era of psychedelic research during the mid-twentieth century and were espoused by diverse figures - from Aldous Huxley to Francis Crick to the Beatles (Goodden 2017; Sessa 2008). Researchers soon picked up on the connection between psychedelics and creativity as demonstrated by myriad articles published during this period (e.g., Harman *et al*. 1966; McGlothlin, Cohen, & McGlothlin *et al*. 1967; Zegans *et al*. 1967; see Sessa 2008, for a review). Today, researchers are revisiting psychedelic drugs' potential for improving creativity. Kuypers *et al*. (2016) found that while under the influence of ayahuasca, participants had increased divergent, but decreased convergent, creativity compared to their pre-ayahuasca session. These results contrast with another study which found improved convergent creativity after ayahuasca ingestion that lasted at least 4 weeks (Uthaug *et al*. 2018). In another study looking at non-acute effects, participants who partook in an ayahuasca retreat demonstrated enhanced creative expression relative to a control group similar in sex and age (Frecska *et al*. 2012). Finally, Prochazkova *et al*. (2018) found that when on "microdoses" of psychedelics (i.e., ~ 1/10th of a standard dose), participants had improved divergent and convergent creativity; however, the results must be interpreted with caution as participants were self-selected and not blind to conditions. It is also important to keep in mind that many of the aforementioned studies lacked adequate control groups given that it is difficult to blind participants between a consciousness-altering drug and placebo (Hendy 2018). Additionally, it is unclear if these effects generalize to older adulthood because no studies to date have directly assessed psychedelics' effects on creativity in this population. The inconclusive results in the literature thus far can most likely be attributed to differences in timing (i.e., acute vs. non-acute effects) and dosage. However, the wealth of anecdotal reports and promising findings from preliminary empirical research suggest a relationship between psychedelic use and creativity. Thus, although more research is needed, psychedelic drugs may have the potential to compensate for declines in creativity in older age and stimulate new ideas or styles of thinking (Uthaug *et al*. 2018).

Psychedelics may also have effects on age-related cognitive changes in areas such as executive functioning. In a study examining regular ayahuasca users with controls who were similar in sex, age, education, and income, Buoso and colleagues (Bouso *et al*. 2012) found that the users performed better on the Stroop task, the Wisconsin Card Sorting Test (WCST), the Letter-Number Sequencing task, and the Frontal Systems Behavior Scale. These findings suggest that psychedelic use is associated with increased working memory and set-shifting, which are two key components of executive functioning. Consistent with these results, another study found greater working memory performance in psychedelic drug users and a trend towards improved scores on the WCST relative to a control group that was matched for sex, age, income, and verbal and fluid intelligence quotient (IQ) scores (Bouso *et al*. 2015). Given the correlational nature of these studies, future experimental research is needed to delineate causation as well as test whether these improvements are maintained as individuals age. However, given that psychedelics stimulate plasticity (Ly *et al*. 2018) and enhanced plasticity has been shown to improve executive functioning (Selemon 2013), there is reason to expect that psychedelics have a causal effect on executive function. These results, in tandem with studies on psychedelics and creativity, suggest that psychedelics may be able to attenuate some of the cognitive changes related to older adulthood.

Affective Parallels

A striking parallel between psychedelic drugs and older adulthood regards their connections with affective processing. As previously mentioned, late-life can be associated with a number of affective shifts, including changes in openness to experience (Donnellan and Lucas 2008), empathy (Grühn *et al*. 2008), pessimism (Chang *et al*. 2013), rates of depression/suicide (De Leo and Meneghel 2001; Kumar *et al*. 2015; Wang and Blazer 2015), and meaningful experiences (Baum 1988). These affective changes can have considerable implications for overall well-being and quality of life in the elderly (Chang *et al*. 2013). For instance, treating depression decreases the severity of cognitive decline in the elderly (Mossello *et al*. 2008) and increased openness to experience is related to successful aging (Gregory *et al*. 2010). For those wanting to counter affective changes documented in older adulthood, evidence is mounting that psychedelics induce several opposing effects.

One affective change that has been consistently related to psychedelics is increased openness to experience. MacLean *et al*. (2011) found that participants reported increased openness after a high-dose psilocybin session relative to a control methlyphenidate session, and these changes were maintained for at least 1 year. Although this study was limited by a selection bias (i.e., recruitment materials advertised that participants would be taking psilocybin), subsequent studies have replicated increased openness after psychedelic use (Bouso *et al*. 2018; Erritzoe *et al*. 2018; Lebedev *et al*. 2016). Studies in this area could also be tainted by experimenter bias: given the stigma historically associated with these drugs, potentially only researchers with deep intrinsic interest in psychedelics would be willing to risk their professional credibility and resources by entering the field. This could bias the type of questions researchers study with the drugs (i.e., there could be a lack of studies on negative outcomes related to psychedelics). Lastly, it is possible that participants showed increased openness because they were on an illicit drug rather than because of psilocybin per se. That is, perhaps after having an enjoyable experience with something highly stigmatized, individuals may wonder what other stigmatized/disconcerting activities they should also be open to. Changes in openness may nevertheless have exponential downstream effects on other cognitive and affective outcomes, such as creativity (Silvia *et al*. 2009). Further, psychedelic use has been shown to increase emotional empathy (Pokorny *et al*. 2017), which may also be related to changes in openness. Speculatively, it seems that increased openness to experience could also increase the number of meaningful experiences in older adulthood. In any case, the changes in openness induced by psychedelics seem to run counter to the changes seen in late-life.

Perhaps the most rapidly growing area of psychedelic research is in their treatment for affective disorders like depression (Griffiths *et al*. 2016; Carhart-Harris *et al*. 2016; Ross *et al*. 2016; Uthaug *et al*. 2018). Indeed, in the USA, the FDA recently designated psilocybin to "breakthrough therapy" status for treatment-resistant depression (Bauer 2019), which should expedite future research in this area. Given the wide variety of negative outcomes associated with depression, this research could have important implications for older adults. In one stark example, Griffiths *et al*. (2016) found that following psilocybin-assisted psychotherapy, 80% of their depressed patients showed a reduction in symptoms that were maintained for at least 6 months after their sessions. Ross *et al*. (2016) concurrently found similar findings (i.e., 60-80% of patients had a reduction in symptoms 6.5 months after their sessions) in a rigorous double-blind, placebo-controlled, and crossover trial of cancer patients experiencing end-of-life distress. The findings from the Griffiths and Ross experiments are particularly pertinent to older adults given the average age in each of their studies was 56 years old. Further, while older adults are generally more pessimistic (Chang *et al*. 2013), psychedelic therapy has been shown to reduce pessimism and these changes are related to therapeutic outcomes with depression (Lyons and Carhart-Harris 2018). Heightened emotion regulation has also been linked with healthy aging (Suri and Gross 2012) and is increased in male psychedelic users compared to male non-users (Thiessen *et al*. 2018). Lastly, correlational research shows a negative relationship between psychedelic use and psychological distress and suicidal behaviors (Hendricks *et al*. 2015). Altogether, there is growing evidence that these drugs induce changes in emotional processing that oppose many changes seen in late-life.

Another affective connection between psychedelics and older adults regards meaningful experiences. As previously mentioned, the elderly report a paucity of meaningful events in later life (Baum 1988). Intuitively, a lack of meaningful experiences may be a contributing factor in pessimism, late-life depression, and increased rates of suicide in the elderly (Heisel and Flett 2008). Indeed, low meaning in life has been linked with increased suicide ideation (Heisel and Flett 2008), and interventions aimed at increasing meaning improve wellbeing in the elderly (Breitbart *et al*. 2015). Recent findings from psychedelic science suggest that psychedelic drugs may be able to treat this lack of meaningful experiences. In what is perhaps the seminal psychedelic study of the twenty-first century so far, Griffiths *et al*. (2006) found in their double-blind experiment that two thirds of their participants rated their psilocybin session as being one of the top five most meaningful experiences in their life - comparable to events like the birth of a child or death of a parent. Further, 38% said it was one of their top five most spiritually significant experiences, and 79% of participants in this study rated that the experience improved their sense of well-being or life satisfaction "moderately" or "very much." The results illustrate that psychedelic drugs can induce experiences that are incredibly meaningful, even spiritual; this could have monumental implications for older adults suffering from a lack of meaningful experiences.

Relatedly, psychedelics' effects on end-of-life distress and palliative care is another area of current study (Kelmendi *et al*. 2016; Shelton and Hendricks 2016). Although this line of research was predated by similar studies in the first era of psychedelic research (e.g., Cohen 1965; Fisher 1970; Grof *et al*. 1973), improved experimental methodology has greatly advanced our understanding of the role psychedelics can play at the end-of-life. The first study in this area during the current era of psychedelic research was a double-blind, placebo-controlled pilot study which showed modest improvements in measures of well-being (Grob *et al*. 2011). Though limited by a small sample and relatively low dosage of psilocybin, the study was important in reestablishing proof-of-concept and safety protocols. More rigorous studies followed in 2016 as both Griffiths *et al*. and Ross *et al*. found robust decreases in measures of end-of-life distress. Finally, another study found that, in a dose-dependent manner, psilocybin treatment led to increases in life satisfaction, positive attitudes about life, and spirituality (Griffiths *et al*. 2011) - which can be critical factors in healthy aging that buffer against emotional distress (Grob *et al*. 2013).

Potential Mechanisms

Given the sheer number of cognitive and affective changes that have been related to psychedelics, they are each likely supported by distinct and overlapping mechanisms. In this section, we touch on the potential mechanisms underlying the previously mentioned alterations in cognition and affect associated with these substances.

Psychedelic drugs exert their acute effects predominantly through serotonin 5-HT$_{2A}$ receptors (Preller *et al*. 2017; Vollenweider *et al*. 1998). These receptors are widely distributed in the cortex, explaining the diverse effects of psychedelics and play a key role in memory and cognition (Zhang and Stackman Jr 2015). In animal studies, 5-HT$_{2A}$ activation has led to increased cognitive flexibility as well as associative learning (Carhart-Harris *et al*. 2014). Therefore, psychedelics may also affect cognitive flexibility, which could explain their effects on creativity, executive functioning (i.e., set-shifting), openness, and depression. Indeed, Jungaberle *et al*. (2018) noted that cognitive flexibility is generally heightened in psychedelic states. Carhart-Harris *et al*. (2014) proposed an exhaustive model of the effects of psychedelic drugs that begins at the 5-HT$_{2A}$ receptor level and builds into the desynchronization of higher-level networks in the brain (see Carhart-Harris 2018, 2019, for further discussion of the entropic brain hypothesis).

Another - more speculative - explanation for the cognitive changes related to psychedelics is increased neurogenesis and neuroplasticity (Lima da Cruz *et al*. 2018). Decreased neurogenesis is thought to be a key factor underlying declines in cognition in older adults as neurons that die off are not replaced as efficiently (Galvan and Jin 2007; Xu *et al*. 2015). Additionally, Goh and Park (2009) argued that enhanced neuroplasticity could act as a compensatory response in the aging brain, and they suggested that interventions should be identified that can stimulate plasticity. Psychedelic drugs are intriguing candidates for inducing these critical changes in the brain. Several studies in recent years have shown that administering psychedelic drugs in vitro (Catlow *et al*. 2013) and in vivo (Catlow *et al*. 2016; Lima da Cruz *et al*. 2018; Morales-García *et al*. 2017) stimulates neurogenesis. Further, a recent paper in *Cell Reports* demonstrated that psychedelics increased neuroplasticity and synaptogenesis (Ly *et al*. 2018). However, this mechanism remains uncertain until the results are replicated in human samples. Increased neurogenesis and neuroplasticity could explain some of the affective changes that have been related to psychedelics. Atrophy of prefrontal cortex neurons is thought to be a contributing factor to depression (Christoffel *et al*. 2011; Ly *et al*. 2018), and Jacobs *et al*. (2000) speculated that enhancing neurogenesis could aid in the recovery from depression. Given that relatively few interventions have been identified that can increase neurogenesis and plasticity, psychedelic drugs' potential in this domain is an important area of future research and this mechanism could contribute to the cognitive and affective changes (Vollenweider and Kometer 2010).

Some have argued that the increased sense of connectedness resulting from psychedelics underlies much of their therapeutic potential (Carhart-Harris *et al*. 2018). Individuals often report a profound sense of "oneness," ego dissolution, and a loss of a sense of self while on the drugs (Lebedev *et al*. 2015). Validating these anecdotal accounts, several recent studies have shown that the default mode network (DMN), which is fundamental in maintaining a sense of self, is deactivated while on psychedelics (Carhart-Harris *et al*. 2012; Palhano-Fontes *et al*. 2015; Smigielski *et al*. 2019). Millière *et al*. (2018) argue that the functional disintegration of the DMN during psychedelic states can drastically alter aspects of consciousness through transient decreases in self-referential thought and access to autobiographical information, leading to alterations in one's sense of self-identity. This shift in perspective may underlie changes in openness and empathy as individuals become less self-centered and more open to new ways of thinking. Indeed, changes in ego dissolution predicted subsequent increases in openness (Lebedev *et al*. 2016) as well as positive therapeutic outcomes (Griffiths *et al*. 2008; Ross *et al*. 2016). Given that depressed individuals are characterized by more self-referential cognitions and increased DMN activity (Sheline *et al*. 2009), these changes in one's sense of self seem to be an important mechanism underlying clinical changes associated with psychedelic drugs.

Finally, the degree to which one has a "mystical" experience while on the drugs predicts therapeutic outcomes (Garcia-Romeu *et al*. 2019, 2014; Griffiths *et al*. 2016; Roseman *et al*. 2018; Ross *et al*. 2016; Russ *et al*. 2019; Schmid and Liechti 2018) as well as changes in openness (MacLean *et al*. 2011). Mystical experiences are marked by a profound sense of meaning/sacredness, interconnectedness with others and the world, transcendence of time and space, ineffability, and a deep positive mood (Grob *et al*. 2013; Kelmendi *et al*. 2016). Deactivation of the DMN seems to be one component in having a mystical experience (Swanson 2018), which may explain their shared therapeutic outcomes. Declines in DMN activity are consistent with the decreases in self-referential processing as well as feelings of spacelessness and timelessness associated with mystical experiences (Barrett and Griffiths 2017). Griffiths *et al*. (2011) found that the dosage of psilocybin which yielded the highest probability of a mystical experience was also the dosage participants reported as the most personally meaningful, spiritually significant, and the session which they would most want to repeat given the opportunity. Similarly, Grob *et al*. (2013) argued that the mystical experience is critical in mediating psychedelic-related benefits, particularly in palliative care. They hypothesized that the patient's self-image can be "recalibrated" during this time of transcendence, such that they adopt a broader existential perspective and the concept of death is less anxiety-provoking. Psilocybin's tendency to increase a sense of continuity after death (Griffiths *et al*. 2011) may also be contributing to declines in end-of-life distress.

Safety

A natural concern when considering administering illicit drugs is safety. It is not recommended for seniors (or anyone) to take these substances unsupervised or without professional medical consultation. The tendency for psychedelics to induce acute increases in blood pressure, body temperature, heart rate, plasma cortisol, and epinephrine should be considered by consulting physicians (Nichols 2016). Current researchers put a strong emphasis on mentally preparing individuals for the experience, and they stress that the benefits derived from psychedelic-assisted psychotherapy sessions may not generalize to recreational psychedelic use (Honig 2019). That being said, correlational studies have shown that psychedelic use is not linked to mental health problems or suicidal behavior (Johansen and Krebs 2015), and their use is linked to reduced psychological distress and suicidality (Hendricks *et al*. 2015). Further, Bouso *et al*. (2012) found that regular ayahuasca users scored lower on every psychopathology measure they administered compared to non-users who were similar in sex, age, education, and income. When evaluating the abuse potential of psilocybin according to the 8 factors of the U.S. Controlled Substances Act, Johnson *et al*. (2018) concluded that there is limited harm associated with the drug. Lastly, rather than being a gateway drug, psychedelic users are at a 40% reduced risk of abusing opiates in the last year (Pisano *et al*. 2017), and they have not been shown to induce dependence (Rucker *et al*. 2016). Given the rapidly rising rates of opiate abuse in older adults (SAMHSA 2017), this could be another potential benefit for this population. This is not to say that psychedelics are risk-free; they can induce experiences that are incredibly psychologically challenging, particularly when used in the absence of proper "set" and "setting" (Barret *et al*. 2016). However, limited harm has been reported in the new era of psychedelic research, which utilizes rigorous preparation, support, and integration procedures. Indeed, Ross *et al*. (2016) noted that in the new era of psychedelic research, over 2000 participants have been run through carefully monitored sessions with zero long-term aversive side effects reported (see Johnson *et al*. 2008 for safety guidelines).

Future Directions

There are several logistical and practical concerns that must be addressed to implement psychedelic treatment for age-related changes in cognition and affect. First, researchers need to identify when the best time is for individuals to take these substances to maximize their therapeutic properties. Perhaps taking them in early adulthood can buffer against downstream effects from chronic traits that psychedelics have been shown to change (i.e., creativity, executive functioning, openness to experience, depression, pessimism). On the other hand, it is still unclear how long psychedelic-related changes in cognitive/affective processing are maintained. While several contemporary studies have demonstrated changes lasting for at least a year (Gasser *et al*. 2014, 2015; Griffiths *et al*. 2008, 2011) and there is evidence that some changes endure as long as 25 years after a single session (Doblin 1991), other studies suggest that "booster" sessions may be valuable (Barbosa *et al*. 2009; Noorani *et al*. 2018). It seems likely that more robust longitudinal studies will emerge as the number of experimental studies has skyrocketed in recent years, and these can inform researchers about optimal timing, dosage, and number of sessions required.

The extent to which all of these changes generalize to older adults is another remaining question. Given the unique changes and life challenges associated with older adulthood, the treatments designed for younger individuals would not be expected to always be appropriate for older adults (and vice versa). For example, treatments like cognitive behavioral therapy (CBT) for mental illness are equally effective in younger and older adults but administered differently (Laidlaw 2014). Older adult CBT focuses on additional concerns such as mobility, bereavement, loneliness, and medical issues that are not common concerns for younger adults. In the same way, psychedelic treatment for young adults may differ in its implementation compared to older adults, and this warrants future study. In any case, some contemporary psychedelic studies have incorporated older adults and demonstrated a variety of positive outcomes (Griffiths *et al*. 2016; Ross *et al*. 2016); thus, there is emerging evidence that administering psychedelics during late-life can lead to cognitive and affective changes.

Conclusion

In short, the reviewed literature demonstrates robust theoretical links between psychedelics and changes in cognition and affect associated with older age. Though many older adults suffer declines in creativity and executive functions, psychedelics have been shown to boost creativity and have been related to improved executive functioning. Older adulthood has also been associated with reduced openness to experience, empathy, and meaningful experiences, all of which can be increased by psychedelic drugs. Their compelling therapeutic potential for depression, pessimism, suicide, and palliative care may also be of benefit to the elderly. Enhanced neurogenesis, neuroplasticity, connectedness, and mystical experiences have been argued to underlie many of the cognitive and affective changes. Finally, recent studies endorse that these drugs are relatively safe when used with professional preparation and supervision. Given that several of these studies have utilized older adults, it seems that they can be implemented into this population. Altogether, the prior research supports that using psychedelics to treat age-related changes in cognition and affect can be a viable, and likely impactful, area of study. This review proposes a novel area of research, and the findings from our critical analysis of the background literature reveal that researchers should consider self-selection biases, experimenter biases, standardized dosages, control groups, and generalizability to improve future experimental methodology in psychedelic science.

Abstract

Background: Psychedelic therapy is gaining recognition and the nature of the psychedelic experience itself has been found to mediate subsequent long-term psychological changes. Much emphasis has been placed on the occurrence of mystical-type experiences in determining long-term responses to psychedelics yet here we demonstrate the importance of another component, namely: emotional breakthrough.

Methods: Three hundred and seventy-nine participants completed online surveys before and after a planned psychedelic experience. Items pertaining to emotional breakthrough were completed one day after the psychedelic experience, as were items comprising the already validated Mystical Experience Questionnaire and the Challenging Experience Questionnaire. Emotional breakthrough, Mystical Experience Questionnaire and Challenging Experience Questionnaire scores were used to predict changes in well-being (Warwick-Edinburgh Mental Well-being Scale) in a subsample of 75 participants with low well-being baseline scores (≤45).

Results: Factor analyses revealed six emotional breakthrough items with high internal consistency (Cronbach's alpha=0.932) and supported our prior hypothesis that emotional breakthrough is a distinct component of the psychedelic experience. Emotional breakthrough scores behaved dose-dependently, and were higher if the psychedelic was taken with therapeutic planning and intent. Emotional breakthrough, Mystical Experience Questionnaire and Challenging Experience Questionnaire scores combined, significantly predicted subsequent changes in well-being (r=0.45, p=0.0005, n=75), with each scale contributing significant predictive value. Emotional breakthrough and Mystical Experience Questionnaire scores predicted increases in well-being and Challenging Experience Questionnaire scores predicted less increases.

Conclusions: Here we validate a six-item 'Emotional Breakthrough Inventory'. Emotional breakthrough is an important and distinct component of the acute psychedelic experience that appears to be a key mediator of subsequent longer-term psychological changes. Implications for psychedelic therapy are discussed.

Keywords: Psychedelics, catharsis, emotion, therapy.

Introduction

Psychedelic therapy is a re-emerging paradigm within mental health research (Schenberg, 2018). It is hypothesised that both biological and psychological processes play a role in this treatment, potentially working synergistically to determine therapeutic outcomes (Carhart-Harris, 2018; Carhart-Harris *et al.*, 2017b). From a purely psychological perspective, most studies to-date have focused on the involvement of the mystical-type experience in determining long-term responses to psychedelics (Bogenschutz *et al.*, 2015; Dakwar *et al.*, 2014; Erritzoe *et al.*, 2018; Garcia-Romeu *et al.*, 2014; Griffiths *et al.*, 2016; Johnson *et al.*, 2016; Klavetter and Mogar, 1967; Kurland *et al.*, 1972; MacLean *et al.*, 2011; O'Reilly and Funk, 1964; Pahnke *et al.*, 1970; Richards *et al.*, 1977; Roseman *et al.*, 2017; Ross *et al.*, 2016) and see Stace (1960) for some classical texts relevant to the mystical experience. Influential measures used to operationally define the mystical experience include factors within the altered states of consciousness questionnaire (Dittrich, 1998; Studerus *et al.*, 2010) and the more recently validated Mystical Experience Questionnaire (MEQ) (MacLean *et al.*, 2012; Pahnke and Richards, 1966). It is now a well-replicated finding that the quality of the acute psychedelic experience is a key determinant of longer-term responses to psychedelics - and the mystical type experience seems to be relevant and important in this regard. However, this does not imply that the construct is well-defined, or that it is the sole, or indeed, primary determinant of long-term psychological outcomes.

Another key component of the acute psychedelic experience that has been found to be influential in determining long-term responses is the challenging experience (CE) (Barrett *et al.*, 2016). Perhaps the best available tool for measuring CEs is the recently validated Challenging Experience Questionnaire (CEQ). This scale was developed with the intention of quantifying challenging emotions such as grief, fear, paranoia, etc.

(Barrett *et al*., 2016). Recent studies have suggested that higher scores of the CEQ and other measures of CE can predict worse longer-term mental health outcomes, thus suggesting that CE might be counter-therapeutic and perhaps even iatrogenic (Barrett *et al*., 2016; Carbonaro *et al*., 2016; Haijen *et al*., 2018; Roseman *et al*., 2017), although there are some contradictory findings in this regard, suggesting a more complex relationship (Barrett *et al*., 2016; Carbonaro *et al*., 2016). A major limitation of the CEQ however, is that it measures different challenging emotions and/or memories without addressing their potential resolution, and consequently is not able to quantify the potential clinical value of accepting and/or overcoming the relevant challenges (Watts *et al*., 2017).

Here, we endeavoured to examine a third potential mediator of longer-term responses to psychedelics, based on the assumption that the MEQ and CEQ do not fully or clearly capture the phenomenon of overcoming challenging emotions/memories and thereby experiencing emotional release or breakthrough. The phenomenon of emotional breakthrough (EB) overlaps to some extent with the psychoanalytic notion of catharsis (Breuer and Freud, 1895; Jackson, 1994). We call the questionnaire we have constructed and validated here, the Emotional Breakthrough Inventory (EBI). Unlike the CEQ, which appears to be a 'negative' predictor of clinical outcomes (i.e. higher CEQ scores predict worse mental health outcomes), we theorised that EBI would serve as a positive predictor of mental health, i.e. higher scores would predict better mental health outcomes such as increases in well-being. The development and use of the EBI in intended to supplement the use of the CEQ and MEQ and motivate further critique of all of three measures and the real-world phenomena they are intended to capture.

The most often-used approach in modern psychedelic therapy trials has its basis in work advanced by the collaboratory effort of Al Hubbard, Humphry Osmond and Abram Hoffer in the 1950s (Dyck, 2006; MacLean *et al*., 1961; Osmond, 1957). The focus of the so-called 'psychedelic' model is to use relatively high doses of a given psychedelic to promote the attainment of a powerful self-transcendent state that may be positively transformative in effect. The other major alternative therapeutic model, is the socalled 'psycholytic' (mind-loosening) model. This approach used lower doses of a psychedelic in concert with psychoanalytically oriented psychotherapy. Despite differences, mainly related to dose and number of sessions (i.e. higher doses but fewer sessions in psychedelic therapy), both of the psychedelic and psycholytic models emphasised the importance of emotional release.

One early account of Lysergic Acid Diethylamide's (LSD) therapeutic action stated that drug works to break emotional or memory blocks and 'in almost every case... terminates in psycho-catharsis, [causing] the patient to experience an exhilarating feeling of liberation' (Frederking, 1955: 263). Other psychedelic therapists, with allegiances to varying psychoanalytic schools, shared this appreciation of the importance of EB (Bonny and Pahnke, 1972; Cohen, 1959; Crocket *et al*., 1963; Eisner and Cohen, 1958; Fisher, 2015; Grof *et al*., 1980; Jensen, 1963; Katzenelbogen and Fang, 1953; Leuner, 1961; Martin, 1957; Richards, 2015; Sandison, 1955), and patients often make special reference to it in post-treatment reports (Belser *et al*., 2017; Gasser *et al*., 2014; Watts *et al*., 2017). EBs are often accompanied by and related to personal and interpersonal insights, and are therefore not necessarily transpersonal in the same way - or to the same extent - that mystical-type or peak experiences appear to be (Belser *et al*., 2017; Gasser *et al*., 2014; Grof, 1975; Loizaga-Velder, 2013; Richards, 2015; Watts *et al*., 2017).

The present study sought to develop and validate a brief EBI that is focused and concise in nature. Specifically, we assessed its internal, convergent, divergent and predictive validity. This was done using an online prospective survey in which participants answered questionnaires before and after drug intake in their own environment rather than e.g. in a laboratory. The sample was self-selecting and comprised mostly of healthy individuals, thus, to combat the issue of floor effects, a well-validated measure of psychological well-being was used as the primary dependent variable and index of post-psychedelic change in psychological/emotional health. We hypothesised that:

- H1: Scores on the EBI will increase in a dose-dependent manner.
- H2: A therapeutic context (therapeutic intention before drug intake and a therapeutic setting) will be associated with higher EBI scores.
- H3: EBI scores will significantly discriminate from MEQ and CEQ scores.
- H4: EBI will predict changes in well-being.
- H5: A model incorporating EBI, MEQ and CEQ will predict changes in well-being, with EBI performing

at least as well as the MEQ and CEQ.

Method

The study was approved by Imperial College Research Ethics Committee and the Joint Research Compliance Office at Imperial College London and carried out in accordance with principles of good clinical practice. Written informed consent was obtained from all subjects. The original survey has now closed but revised and still active versions of related surveys can be found here at www.psychedelicsurvey.com.

Software

Statistical analyses were conducted on SPSS 25 and Matlab 2017.

Design

The data presented in this article was collected as part of a larger prospective study (Haijen *et al.*, 2018). Only elements of the design and data that are relevant to this article are presented here. Data was collected from psychedelic 'users' in a non-controlled, naturalistic and observational manner. Data was collected on-line, through the website and software platform psychedelicsurvey.com. The study was advertised via social media platforms. The baseline time-point was one week before a planned psychedelic experience and the key end-point was two weeks post the relevant experience. The following data were collected at baseline: demographics, intentions for the experience (see below), and the Warwick-Edinburgh Mental Well-being Scale (WEMWBS) which served as the primary and sole dependent variable. Retrospective reports of the acute experience were answered one day after the relevant psychedelic experience. These included: EBI, MEQ, CEQ, dose and whether the experience took place in a therapeutic setting (see below). Longterm outcomes were collected two weeks after the experience. The WEMWBS serving as the sole dependent variable for the present analysis. Data of 379 participants have been used for most of the analysis in this article, however, a subset of 75 participants with low well-being baseline scores (WEMWBS≤45) have been used for prediction of changes in well-being (more information below).

Item selection and face validity

The items of EBI were devised based on interview content from our previous psilocybin for treatment-resistant depression trial (Watts *et al.*, 2017) and knowledge of the extensive literature and personal observations on the phenomenology of the psychedelic experience and its therapeutic application (Belser *et al.*, 2017; Bonny and Pahnke, 1972; Cohen, 1959; Crocket *et al.*, 1963; Eisner and Cohen, 1958; Fisher, 2015; Frederking, 1955; Gasser *et al.*, 2014; Grof *et al.*, 1980; Jensen, 1963; Katzenelbogen and Fang, 1953; Leuner, 1961; Martin, 1957; Richards, 2015; Sandison, 1955). Eight initial items were devised (Table 1), out of which two were 'negative' items that required reverse scoring. Items were rated using a visual analogue scale (VAS) (0-100, with incremental units of one) with zero defined as 'No, not more than usually', and 100 defined as 'Yes, entirely or completely'. Five experts (W Richards, R Watts, R Carhart-Harris, J Rucker and L Roseman) assessed the items and revised them if needed. Below are selected quotes that helped inform the construction of EBI items. These derive from interviews with patients (Watts *et al.*, 2017) in our recent psilocybin for treatment-resistant depression trial (Carhart-Harris *et al.*, 2017a). The quotes are from the qualitative analysis of Watts *et al.* (2017), although most were not included in that study.

> 'It felt like a relief, I was getting so emotional, I could feel it all coming out'
>
> 'One emotional song, and I lost control, the song was so sad I started crying uncontrollable, and was terrified by the depth of emotions'
>
> 'It was an emotional purging. The weight and anxiety and overwhelming depression have been lifted'

> 'It was an uncomfortable experience and it got to the point where I got really really angry with it, like something snapped inside my head, and rather than be afraid of it I challenged it and at that point it kind of vanished, it went away'
>
> 'I was weeping, tears were flowing out of me. It wasn't a painful crying, it was like turning on the taps, like a washing, a washing out.'
>
> 'There was a lot of sadness, really really deep sadness: the loss the grief, it was love and sadness together, and letting go, I could feel the grief and then let it go because holding onto it was hurting me, holding me back. It was a process of unblocking'
>
> 'Excursions into grief, loneliness and rage, abandonment. Once I went into the anger it went 'pouf' and evaporated. I got the lesson that you need to go into the scary basement, once you get into it, there is no scary basement to go into [anymore]'
>
> 'I had lost my ability to grieve and cry. [During the dosing session] I cried and that was a cathartic experience for me, a very welcoming sweet experience'.

Table 1. Factor loadings from factor analysis of eight Emotional Breakthrough Inventory (EBI) items.

Item	Factor 1	Factor 2
I faced emotionally difficult feelings that I usually push aside.	**0.788**	0.192
I experienced a resolution of a personal conflict/trauma.	**0.896**	-0.044
I felt able to explore challenging emotions and memories.	**0.866**	-0.076
I was resisting and avoiding challenging feelings throughout, without breakthrough.	0.260	**0.786**
I had an emotional breakthrough.	**0.872**	-0.151
I was able to get a sense of closure on an emotional problem.	**0.889**	-0.185
I felt emotionally stuck throughout, without breakthrough.	0.249	**0.845**
I achieved an emotional release followed by a sense of relief.	**0.848**	-0.194

The extraction method was principal component analysis (PCA). The six bold Items in Factor 1 reflect the final version of the EBI. The remaining bold items in Factor 2 where not used in the final version of EBI. Factor loadings &gt;0.5 are in bold (*n*=379).

Other measures

MEQ (Pahnke *et al.*, 1970; Pahnke and Richards, 1966)

The MEQ was originally developed by Walter Pahnke and Bill Richards based on the anthropological research and theoretical writings of philosopher Walter Stace (1960). Stace studied reports of mystical-type experiences occurring in a variety of religions and identified common experiential components which he argued are universal, i.e. culturally independent and unspecific to any particular religion or philosophical framework (as in Maslow's peak experience (Maslow, 1959; Maslow, 1964), and Huxley's *Perennial Philosophy* (Huxley, 1945)). The MEQ has been revised since its original conception and now includes 30 questions (MacLean *et al.*, 2012) rated according to a five-point Likert scale. It is divided into four subscales: (a) Mystical - which includes arguably the core features of mystical-type experience: named 'unity', 'noetic' and 'sacredness'; (b) Positive-mood; (c) Transcendence of time and space; and (d) Ineffability. The total MEQ score is calculated as the average of all 30 items and then multiplied by 20 to provide a 0-100 value.

CEQ

The CEQ was recently developed to measure the challenging experience (Barrett *et al.*, 2016). The CEQ is derived from 'challenging' items from other psychedelic questionnaires: Hallucinogen Rating Scale (HRS) (Strassman *et al.*, 1994), Altered State of Consciousness questionnaire (ASC) (Dittrich, 1975, 1998), and States of Consciousness Questionnaire (SOCQ) (Griffiths *et al.*, 2006; Pahnke *et al.*, 1969). The CEQ has 26 questions, five-point Likert scale, and is divided into seven dimensions: (a) Isolation, (b) Grief, (c) Physical distress, (d) Fear, (e) Insanity, (f) Paranoia, and (g) Death. Total CEQ score was calculated as the average of all items and then multiplied by 20 to provide a 0-100 value.

WEMWBS

The WEMWBS (Tennant *et al.*, 2007) was designed to measure the psychological well-being of a population. WEMWBS has 14 questions scored using a five-point Likert scale. Scores reflect feelings and thoughts in the two weeks prior to answering the questionnaire. In the present study, the WEMWBS was used to observe potential changes in well-being two weeks after drug intake compared to baseline. Many of the participants had high baseline WEMWBS scores - which created a potential ceiling effect limiting scope for the predicted increases in well-being. We therefore restricted the present analysis to just those subjects who had relatively low baseline well-being scores (≤45, *n*=75) (Taggart *et al.*, 2015) and therefore greater potential for change (normative data based on the general population in England and Scotland showed a mean WEMWBS score of 50.7 (95% confidence interval (CI): 50.3-51.1)).

Drug type

Participants were asked what specific psychedelic they took. Options included: (a) psilocybin/magic mushrooms/ truffles, (b) LSD/1P-LSD, (c) ayahuasca, (d) DMT/5-5-MeODMT, (e) *Salvia divinorum*, (f) mescaline, (g) iboga/ibogaine or (h) the option to give a free answer.

Drug dose

Drug dose was assessed using a previously implemented approach of estimating dosage in relation to LSD equivalents. The rationale for this is to provide a reference-standard dose that can be compared across different psychedelics (Nour *et al.*, 2016). Options were: a low dose (equivalent to no more than 50 µg of LSD), a moderate dose (equivalent to no more than 100 µg of LSD), a high dose (equivalent to no more than 200 µg of LSD), a very high dose (equivalent to no more than 300 µg of LSD), or an extremely high dose (equivalent to more than 300 µg of LSD).

Therapeutic intention

At pre-drug baseline, participants answered the question 'Can you indicate what your motives are to undergo a psychedelic session/ceremony/experience?' A number of intentions were presented, and participants scored each of them on a four-point Likert scale with the options: 'not at all,' 'somewhat,' 'moderately,' or 'very much.' For this analysis we chose two intentions of interest as potential predictors of EBI scores: the intention to have the experience for (a) 'Therapeutic/ personal growth', and (b) 'To confront difficult emotions'.

Therapeutic setting

Participants answered 'yes' or 'no' to the question 'Was the setting designed and/or prepared with a therapeutic objective in mind?' We hypothesised that those who answered 'yes' here would have higher EBI scores.

Factor analysis and definition of EBI

Scores for the original eight EBI items were subjected to an exploratory factor analysis using principal component analysis (PCA). The appropriate number of factors to be extracted was determined by the scree plot criterion (Cattell, 1966). The PCA yielded two factors (Table 1), out of which only factor 1 with six items was used in further analysis. The internal consistency of the six items was assessed with Cronbach's alpha (Cronbach, 1951).

Discriminant validity

In order to test whether the EBI, and the construct it is intended to sample, is significantly different from the constructs indexed by the MEQ and CEQ, the items of all of the questionnaires were entered into one factor analysis (PCA, 62 items). If EB, and the EBI that samples EB, is insufficiently different from the other questionnaires and the constructs they sample, then the PCA would have been expected to yield just two factors - one containing items of the MEQ and the other containing items from the CEQ, with EBI items loading onto one or both of these two factors. If, however, as predicted, the EBI can be discriminated from the MEQ and CEQ, then the PCA would be expected to discover three independent factors, one of which would contain items of the EBI. A correlation matrix including the EBI and subdimensions of MEQ and CEQ was also calculated to further explore similarities and differences between the three questionnaires and their components.

Predictive validity - changes in well-being

Pearson correlation of the EBI versus ΔWEMWBS was calculated to test whether the EBI could serve as a predictor of clinical changes (*n*=75). Furthermore, a multiple regression was calculated with ΔWEMWBS as the dependent variable and the EBI, MEQ and CEQ as independent variables (*n*=75). Beta coefficients were calculated for each of the questionnaires to assess the contribution of each of the questionnaires to explaining changes in the dependent variable (ΔWEMWBS). If significant beta coefficients were found for scores on all of the questionnaires, this would demonstrate the significant added value of each of the three questionnaires and the variance they can explain when combined. We hypothesised that the beta coefficients of EBI and MEQ would be positive predictors of changes (increases) in WEMWBS scores whereas CEQ scores would be negative predictors of changes in well-being.

Results

Demographics

See Table 2 for the demographics of 379 participants who completed EBI and of a subsample of 75 participants with $\text{WEMWBS}_{\text{baseline}} \leq 45$.

Factor structure

The eight original EBI items were entered into a PCA. The Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy was found to be 0.877, and Bartlett's test of sphericity was significant (χ^2 (28) =2005.9, $p<0.0001$) confirming that the data was suitable for factor analysis (Budaev, 2010). Inspection of the scree plot using Cattell's criterion (Cattell, 1966) supported a two-factor model (Table 1). The first component explained 57.1% of the variance and the second explained 18.3%. Other components explained <8% of the variance. Commonality values (the variance of a variable which is explained by the factors) ranged from 65.7-82.5%. Factor 1 comprised of six items, and factor 2 comprised of the two negative, reverse scored items. Originally, we theorised that all items would load into one single factor with the negative items negatively loading on to this. Results revealed that this is not the case, however, and instead the two negative items load onto a sufficiently distinct factor. We therefore decided not to use these two negative items in the final version of EBI.

Table 2. Demographics.

Total		*n*=379	*n*=75
Gender	Male	252 (66.5%)	57 (76%)
	Female	97 (25.6%)	18 (24%)
	Other	2 (0.5%)	0
	Blank	28 (7.4%)	0
Age		30.6±11.0	29±9.4
Educational level	Left school before age 16 years without qualifications	7 (1.8%)	3 (4%)
	Some high school/GCSE level (in UK)	23 (6.1%)	4 (5.3%)
	High school diploma/A-level education (in UK)	47 (12.4%)	10 (13.3%)
	University (or equivalent)	74 (19.5%)	18 (24%)
	Bachelor's degree (or equivalent)	121 (31.2%)	29 (38.7%)
	Post-graduate degree (e.g. masters or doctorate)	79 (20.1%)	11 (14.7%)
	Blank	28 (7.4%)	0
Employment status	Student	124 (32.7%)	17 (22.7%)
	Unemployed	33 (8.7%)	14 (18.7%)
	Part-time job	55 (14.5%)	16 (21.3%)
	Full-time job	133 (35.1%)	27 (36%)
	Retired	6 (1.5%)	1 (1.3%)
	Blank	28 (7.4%)	0
Nationality	United Kingdom	74 (19.5%)	19 (25.3%)
	United States of America	97 (25.6%)	21 (28%)
	Denmark	42 (11.1%)	4 (5.3%)
	Germany	21 (5.5%)	0
	Canada	13 (3.4%)	5 (6.6%)
	Other (38 other nationalities)	104 (27.4%)	26 (34.8%)
	Blank	28 (7.4%)	
Psychiatric history	Has been diagnosed with at least one psychiatric illness in the past[a]	116 (30.6%)	38 (50.7%)
	Never been diagnosed with a psychiatric illness	235 (62%)	37 (49.3%)
Previous psychedelic drug use	Never (psychedelic naïve)	42 (11.1%)	11 (14.6%)
	Once	20 (5.3%)	7 (9.3%)
	2-5 times	71 (18.7%)	22 (29.3%)
	6-10 times	54 (14.2%)	15 (20%)
	11-20 times	57 (15%)	7 (9.3%)
	21-50 times	63 (16.6%)	8 (10.6%)
	51-100 times	19 (5%)	4 (5.3%)
	More than 100 times	25 (7%)	1 (1.3%)
	Blank	28 (7.4%)	

Absolute frequencies and means±standard deviations are presented in the table. Numbers in the brackets show the percentages of the absolute frequencies. The column with *n*=379 is the whole population in this paper, while the column with *n*=75 is of the subpopulation with Warwick-Edinburgh Mental Wellbeing Scale (WEMWBS)≤45.[a] Psychiatric illnesses include major depressive disorder, bipolar disorder, schizophrenia, anxiety disorder, substance abuse disorder, alcohol dependence, hallucinogen persisting perception disorder, psychotic disorder, personality disorder, attention deficit hyperactivity disorder, obsessive compulsive disorder and eating disorder.

Internal consistency

After discarding the two negative items, the resulting six-item EBI displayed a very high internal consistency (Cronbach's alpha=0.932) (Cronbach, 1951). The average of the six items showed a high correlation with factor 1 score (*r*=0.996, *p*<0.0001) and therefore the average of the six items was used as the total EBI score in further analysis. The mean of EBI scores was significantly higher than 0 (EBI=43±31.5, skewness=0.165, kurtosis=-1.3, *p*<0.0001, one sample *t*-test, *n*=379). The mean MEQ score was 57±22.63. The mean CEQ score was 19.7±16.4. See violin plots (Hintze and Nelson, 1998) of EBI, MEQ and CEQ in Figure 1.

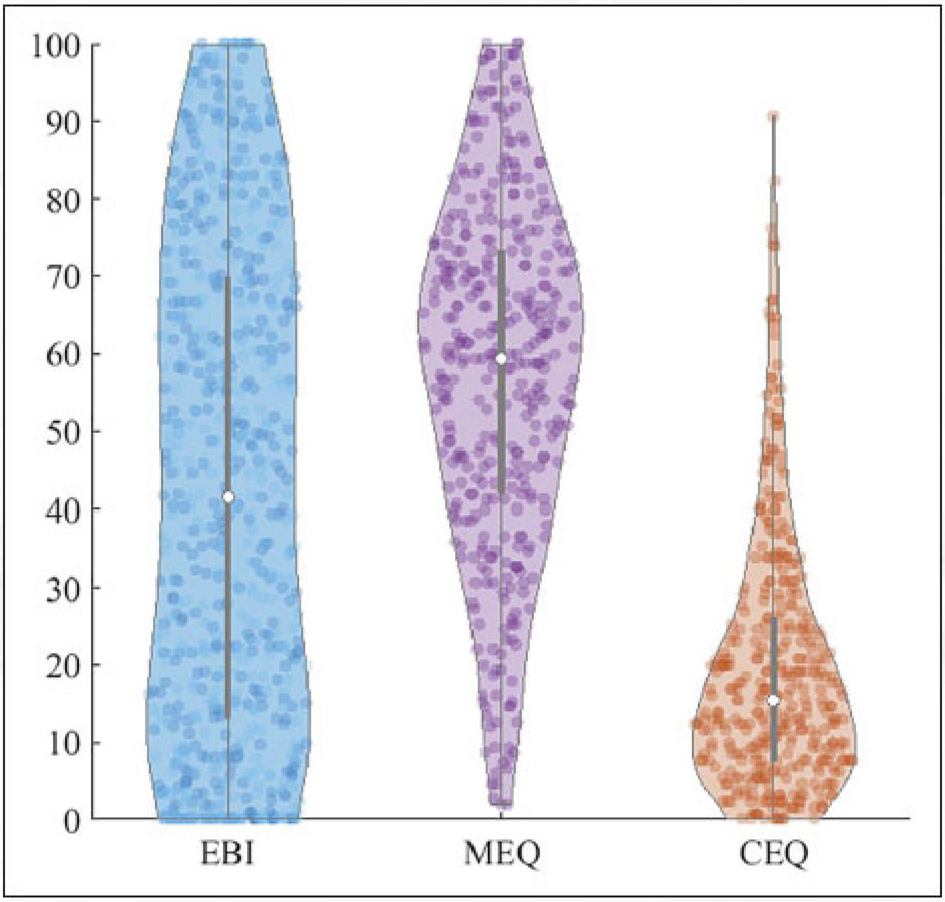

Figure 1. Violin plots of Emotional Breakthrough Inventory (EBI), Mystical Experience Questionnaire (MEQ) and Challenging Experience Questionnaire (CEQ). Total scores of each questionnaire are spread along the y axis. Violin plots are similar to box plots but show also probability density in different values (the width of the plot). The white circle and the thick line are a boxplot in which the white circle is the median and the thick line is the interquartile range (*n*=379).

Predictive validity - dose, therapeutic intention and setting

As predicted, EBI scores significantly (positively) correlated with (estimated) drug dose (r_s=0.192, *p*=0.0001, one-tail, *n*=379). Baseline ratings of therapeutic intention and ratings of willingness to confront difficult emotions significantly correlated (positively) with EBI scores (r_s=0.256 and r_s=0.279, respectively, *p*<0.0001, one-tail, *n*=351). Participants who endorsed the view that the setting for their experience was designed with a therapeutic objective in-mind had higher EBI scores (EBI=47.9±30.1, *n*=144) than those who felt the setting for their experience was not therapeutic in nature or design (EBI=31.6±29.1, *n*=168) (*p*<0.0001, Cohen's *d*=0.55, independent samples *t*-test, one-tail).

Discriminant validity

To demonstrate that the EBI is a novel measure that can be discriminated from the MEQ and CEQ, all of the 62 items from MEQ, CEQ and EBI were entered into a single factor analysis (PCA) (Table 3). The KMO measure of sampling adequacy was 0.941, and Bartlett's test of Sphericity was significant ($\chi^2_{(1891)}$=19829, *p*<0.0001) confirming that the data was suitable for factor analysis (Budaev, 2010). Inspection of the scree plot using Cattell's criterion (Cattell, 1966) supported a model of three factors. The first component explained 31.3% of the variance, the second explained 15.4% of the variance, and the third explained 6.1% of the variance. Other components explained <4% of the variance in the sample. Commonality values ranged from 43.7-81.5%. The first factor contained high loadings from MEQ items, and relatively high loading from EBI items as well. The second factor contained high loadings from CEQ items alone, and the third factor contained high loading from EBI items alone (without any MEQ or CEQ items). These results suggest that for some subjects, EB was accompanied by mystical-type phenomena (and vice versa), whilst for others, EB was distinct from either classical challenging and/or mystical-type phenomena. Note that the relatively low percentage of variance explained by component 3 is probably due to the relatively few EBI items when compared with the MEQ and CEQ (i.e. six in the EBI versus 26 and 30 the CEQ and MEQ, respectively).

A correlation matrix containing all of the EBI items plus subscales of the MEQ and CEQ is presented in Figure 2. It is apparent that the EBI correlates strongly with all MEQ dimensions and also with the grief dimension of CEQ (a relationship between EBI and grief is also suggested in the factor analysis (Table 3)). Correlations between a given subscale of the MEQ and its other subscales are higher than those with the EBI, suggesting that despite some commonalities, the EBI and MEQ are still measuring sufficiently distinct phenomena.

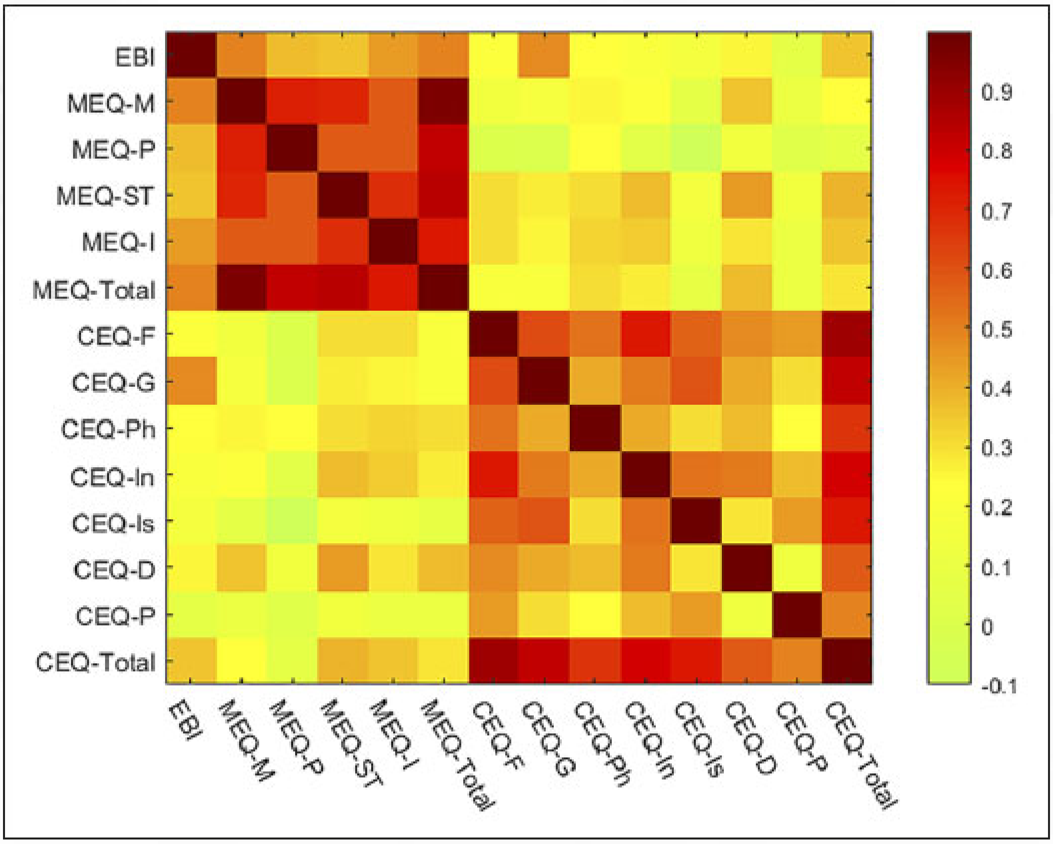

Figure 2. Correlation matrix of Emotional Breakthrough Inventory (EBI), Mystical Experience Questionnaire (MEQ) subscales and Challenging Experience Questionnaire (CEQ) subscales, and CEQ subscales. High Pearson's correlations are observed for EBI with MEQ subscales, and with CEQ_{Grief}. Yet, correlations between any given MEQ subscale and the other MEQ subscales are higher than with the EBI. This analysis, together with the factor analysis in Table 3, suggest that EBI is distinct from MEQ and CEQ (*n*=379).
CEQ-D: Death; CEQ-F: Fear; CEQ-G: Grief; CEQ-In: Insanity; CEQ-Is: Isolation;
CEQ-P: Paranoia; CEQ-Ph: Physical distress; MEQ-I: Ineffability; MEQ-M: Mystical;
MEQ-P: Positive mood; MEQ-ST: Transcendence of space and time.

Predictive validity - changes in well-being

The difference in WEMWBS from baseline (38.8±5.3) to two weeks after the experience (47.9±7.2) was significant (Cohen's d=1.44, p<0.0001, n=75, paired sample t-test). Emotional breakthrough scores significantly correlated with changes in wellbeing (ΔWEMWBS) two weeks after the psychedelic experience (compared with well-being scores at baseline), r=0.294, p=0.005, one-tail, n=75. A multiple regression analysis with ΔWEMWBS as dependent variable and EBI, MEQ and CEQ values as independent variables yielded a strong predictive model (r=0.45, p=0.0005, one-tail, n=75). The standardised beta coefficients for the EBI, MEQ and CEQ were all significant, with the EBI performing as well as the other measures (β_{EBI}=0.29, p=0.017; β_{MEQ}=0.24, p=0.038; β_{CEQ}=-0.35, p=0.002; one-tail). Independent Pearson's correlations between the MEQ and CEQ and ΔWEMWBS were r=0.274, and r=-0.147, respectively. The tolerance measures (collinearity) of EBI, MEQ and CEQ were 0.631, 0.634, 0.814, respectively (tolerance >0.2 means that the independent variables are relatively independent from each other). As a further exploratory analysis, the same regression model was applied to the wider sample regardless of WEMWBS baseline scores. Out of the total sample, 253 participants had completed the WEMWBS at two weeks after the experience. The difference in WEMWBS from baseline (49.5±8.6) to two weeks after the experience (52.7±7.3) for this population was significant as well though with smaller effect size (Cohen's d=0.4, p<0.0001, n=253, paired sample t-test). A multiple regression analysis with ΔWEMWBS as dependent variable and EBI, MEQ and CEQ values as independent variables for these 253 participants yielded a marginally significant result in the same direction as the smaller subsample (r=0.153, p=0.059, one-tail, n=253). The standardised beta coefficients for the EBI, MEQ and CEQ were all marginally significant (β_{EBI}=0.115, p=0.063; β_{MEQ}=0.075, p=0.15; β_{CEQ}=-0.086, p=0.01; one-tail). Independent Pearson's correlations between the EBI, MEQ and CEQ and ΔWEMWBS were r=0.119, r=0.106 and r=-0.019, respectively. Overall, the results of the larger subsample of 253 participants were in a similar direction yet less significant compared to the subsample of 75 participants, and this is probably due to a ceiling effect at the baseline of WEMWBS in the larger subsample. These results confirm that each of the questionnaires contribute added value to the model, whilst being significantly distinct from each other. A natural conclusion from this is that a prediction model containing measures of all three constructs will perform better than a model that neglects any one of them.

Table 3. Factor analysis of Emotional Breakthrough Inventory (EBI), Mystical Experience Questionnaire (MEQ) and Challenging Experience Questionnaire (CEQ). All of the 62 items of the EBI, MEQ and CEQ have been included in a principal component analysis (PCA) which resulted in three factors. The first factor has high loadings of items from MEQ and EBI. The second factor has high loadings of items from CEQ. The third factor has high loading of items from EBI. This analysis, together with the correlation matrix in Figure 2, reveals that EBI is discriminate from MEQ and CEQ. Factor loadings &gt;0.5 are in bold (n=379).

Questionnaire	Subscale	Question	Factor 1	Factor 2	Factor 3
EBI		I faced emotionally difficult feelings that I usually push aside.	**0.524**	0.306	**0.528**
		I experienced a resolution of a personal conflict/trauma.	**0.543**	0.036	**0.656**
		I felt able to explore challenging emotions and memories.	**0.552**	-0.055	**0.613**
		I had an emotional breakthrough.	**0.585**	0.041	**0.631**
		I was able to get a sense of closure on an emotional problem.	**0.515**	-0.057	**0.678**
		I achieved an emotional release followed by a sense of relief.	**0.606**	-0.104	**0.576**
MEQ	Mystical	Freedom from the limitations of your personal self and feeling a unity or bond with what was felt to be greater than your personal self.	**0.755**	-0.309	-0.009
		Experience of pure being and pure awareness (beyond the world of sense impressions).	**0.776**	-0.3	-0.057
		Experience of oneness in relation to an 'inner world' within.	**0.789**	-0.257	-0.056
		Experience of the fusion of your personal self into a larger whole.	**0.778**	-0.271	-0.055
		Experience of unity with ultimate reality.	**0.801**	-0.284	-0.061
		Feeling that you experienced eternity or infinity.	**0.761**	-0.191	-0.127
		Experience of oneness or unity with objects and/or persons perceived in your surroundings.	**0.65**	-0.3	-0.078
		Experience of the insight that 'all is one'.	**0.756**	-0.321	-0.084
		Awareness of the life or living presence in all things.	**0.681**	-0.337	-0.082
		Gain of insightful knowledge experienced at an intuitive level.	**0.705**	-0.28	0.216
		Certainty of encounter with ultimately reality.	**0.682**	-0.283	-0.02

		You are convinced now, as you look back on your experience, that in it you encountered ultimate reality.	**0.653**	-0.294	0.07
		Sense of being at a spiritual height.	**0.715**	-0.299	0.007
		Sense of reverence.	**0.624**	-0.255	-0.015
		Feeling that you experienced something profoundly sacred and holy.	**0.65**	-0.243	-0.008
	Positive mood	Experience of amazement.	**0.675**	-0.291	-0.203
		Feelings of tenderness and gentleness.	**0.596**	-0.374	0.091
		Feelings of peace and tranquillity.	**0.554**	**-0.521**	-0.004
		Experience of ecstasy.	**0.522**	-0.396	-0.097
		Sense of awe or awesomeness.	**0.654**	-0.344	-0.144
		Feelings of joy.	**0.522**	-0.451	-0.098
	Time and space	Loss of your usual sense of time.	**0.632**	-0.059	-0.234
		Loss of your usual sense of space.	**0.648**	-0.049	-0.288
		Loss of usual awareness of where you were.	**0.547**	0.058	-0.319
		Sense of being 'outside of' time, beyond past and future.	**0.742**	-0.05	-0.204
		Being in a realm with no space boundaries.	**0.711**	-0.181	-0.14
		Experience of timelessness.	**0.736**	-0.114	-0.239
	Ineffability	Sense that the experience cannot be described adequately in words.	**0.71**	-0.045	-0.123
		Feeling that you could not do justice to your experience by describing it in words.	**0.711**	-0.074	-0.086
		Feeling that it would be difficult to communicate your own experience to others who have not had similar experiences.	**0.649**	-0.031	-0.086
CEQ	Isolation	Isolation and loneliness.	0.298	**0.647**	-0.001
		Feeling of isolation from people and things.	0.255	**0.623**	-0.025
		I felt isolated from everything and everyone.	0.252	**0.628**	-0.002
	Grief	Sadness.	0.356	**0.542**	0.365
		Feelings of grief.	0.416	**0.502**	0.378
		I felt like crying.	0.423	0.339	0.388
		Feelings of despair.	0.396	**0.662**	0.118

Discussion

Here we sought to devise and carry out validation work on a new scale intended to describe an important and hitherto under-quantified component of the psychedelic experience, the EB. We anticipate that this scale will serve as a useful 'state' predictor of the longer-term psychological outcomes after a psychedelic experience - supplementing already existing state predictor measures such as the MEQ and CEQ. We call this new scale the 'EBI'. Results revealed that (as measured by the EBI) emotional breakthrough is dose dependent and sufficiently different from the mystical-type and challenging experience as indexed by the MEQ and CEQ respectively. Consistent with a major prior hypothesis, we found that (like the MEQ) the EBI significantly predicts post-psychedelic changes in well-being (greater EB, greater increases in well-being) and we also discovered that the EBI does not render either the CEQ or MEQ redundant but rather a multi-factorial predictor model that combines all three measures performs better than any alternative that neglects any one of them. The combined EBI, MEQ and CEQ model is able to predict close to 20% of the variance in well-being changes after a psychedelic experience, a not inconsiderable amount given the relatively 'well' nature of this sample and uncontrolled study design. We also found that both therapeutic intention and therapeutic setting can predict the intensity of EB, suggesting that, as with other components of the acute psychedelic experience, EB is highly influenced by the context in which the psychedelic is taken (Carhart-Harris *et al.*, 2017b; Hartogsohn, 2016, 2017). Taken together, these results support the addition of the EBI to the arsenal of tools used to quantitatively describe the psychedelic experience and predict its longer-term psychological effects.

Modern phenomenological analyses (Belser *et al.*, 2017; Gasser *et al.*, 2014; Watts *et al.*, 2017) and therapists' accounts (Bonny and Pahnke, 1972; Cohen, 1959; Crocket *et al.*, 1963; Eisner and Cohen, 1958; Fisher, 2015; Grof *et al.*, 1980; Jensen, 1963; Katzenelbogen and Fang, 1953; Leuner, 1961; Martin, 1957; Richards, 2015; Sandison, 1955) have tended to recognise the importance of EB within the context of psychedelic experiences and psychedelic therapy; however, a validated quantitative measure of this phenomenon is arguably overdue and there is a significant contemporary need for it. Perhaps due to the relative dearth of psychedelic research since the 1960s and a particular bias common among those few research teams working within the current resurgent era, contemporary researchers have tended to place significant emphasis on the mystical-type experience, in part due to well-replicated findings that its occurrence is predictive of relevant psychological outcomes, such as improvements in well-being (Haijen *et al.*, 2018) changes in personality (MacLean *et al.*, 2011), and improvements in clinical outcomes in patient populations (Roseman *et al.*, 2017).

The present work has demonstrated the added value of measuring EB for predicting subsequent psychological outcomes after a psychedelic experience. However, are there other 'state' and perhaps 'contextual' factors that are also important determinants of longer-term responses to psychedelics - and might there be alternative dependent variables that are differentially influenced by state and contextual predictors? Indeed, these variables may also interact in non-linear ways. We have previously emphasised (Carhart-Harris *et al.*, 2017b), and sought to measure and demonstrate, the influence of contextual factors such as the presence of others, associated therapeutic alliance, a therapeutic intention and setting and a willingness to surrender or 'let-go' to the psychedelic experience on longer-term psychological outcomes, and found them to be important (Haijen *et al.*, 2018). Like 'state' predictors of long-term responses, it is logical to see these factors as mediators of the relevant changes, as they are temporal antecedents of them. Other factors we predict may be important for influencing long-term changes include psychological insight and psychological integration. Insight is a phenomenon that may occur acutely in a state-like fashion (like EB) but could only be more protracted, crystallising in the days to weeks following a psychedelic experience. Integration is another protracted phenomenon that may have no clear end-point as such.

Much more work is needed to understand the neurobiology of the entire psychedelic psychotherapy process and this will naturally require brain imaging at various time points: before, during and after a specific psychedelic experience. Further discussion of this topic is beyond the remit of the present article, only to say that there is some evidence that the magnitude of increased brain entropy, a known biomarker of the psychedelic state, has been found to be predictive of subsequent psychological changes (increased trait 'openness') over a consistent time-scale as was measured here in relation to well-being (Lebedev *et al.*, 2016).

Finally, we advocate looking at other dependent variables than just well-being. Well-being is a useful index of mental health in general populations (Tennant *et al.*, 2007) but it may be that certain psychiatric disorders and/or symptom clusters behave differently in their relation to predictor variables. This is something we intend to investigate more fully in future analyses plus new and on-going studies.

Our novel analysis is part of an effort to elucidate the importance of the psychological mechanism of psychedelics alongside their pharmacological uses, and by doing so to emphasise the importance of the context in which these drugs are taken. That is to say that affirming that the experience mediates the clinical outcomes, means that the regular clinical context will have to be modified to accommodate psychedelics as an effective psychopharmacological intervention within psychiatry. On that note, there is a lesson from history we would like to bring to readers' attention before closing: psychedelic therapy was once a relatively widely practised intervention in Western psychiatry before opinion shifted against it (Baum, 2016; Grinspoon and Bakalar, 1979). As the pharmacological revolution in psychiatry gathered momentum in the 1960s and the thalidomide scandal occurred at a related time, regulations on experimental medicines tightened, as did the methods for assessing their safety and efficacy (Oram, 2012). Within this climate, some efforts were made to extricate the basic pharmacological action of LSD from the psychotherapeutic manner in which it was typically administered, e.g. by giving the drug in a psychologically 'sterile' environment (Ludwig, 1985). In at least one published study, patients treated with LSD were placed in a belt that restrained them to their bed (Johnson *et al*. 1969). Unsurprisingly, such efforts to 'neutralise' context (which is, of course, a misnomer) tended to reveal that LSD without contextual support does not nearly have the same therapeutic value and safety profile as LSD given with therapeutic support (Oram, 2012, 2014). These results, combined with the spread of unfounded but nonetheless affecting misinformation about LSD (Dishotsky *et al*., 1971) plus a tightening of legislation on drugs of potential misuse, best exemplified by the 1970 Controlled Substances Act (1970), signalled the demise of psychedelic psychotherapy. The present study's analyses confirm the findings of other analyses (Dimascio and Klerman, 1960; Haijen *et al*., 2018; Hyde, 1960; Lasagna, 1963; Leary *et al*., 1963; Studerus *et al*., 2012) that context is an essential component of the psychedelic model (Carhart-Harris *et al*., 2017b; Hartogsohn, 2017; Leary *et al*., 1963) and that if one wishes to promote a positive therapeutic response to a psychedelic, then heeding and optimising the role of certain contextual components is entirely necessary, whereas neglecting them is bad practice if not unethical. Our hope is that psychedelic therapy of the future can be done in a way and a context that encourages and allows the free release of emotion, e.g. using tools such as music (Barrett *et al*., 2018; Bonny and Pahnke, 1972; Kaelen *et al*., 2017), empathic listening and purposefully designed supportive environments, even if this presents a significant challenge to the conventions of mainstream medicine:

> [Practicing psychedelic therapy here] has transformed the entire hospital, because the whole atmosphere engendered by LSD has spread throughout the hospital and, in fact, forms an essential part of the hospital culture. If LSD is given in a large institutional setting, treatment will be ineffective unless this transformation has occurred.
>
> British psychiatrist Ronald Sandinson (1916-2010) cited in Abramson (1960: 15)

Three limitations of the present study should be noted. First, the present study's population contained mostly healthy experienced psychedelic users, and therefore the results do not necessarily apply to clinical population (Haijen *et al*., 2018). In these users the outcomes in well-being might be related to the expectation build around psychedelic use in the psychedelic culture and literature. Furthermore the pharmacological mechanism of psychedelics might be different in these users due to greater exposure to this class of drugs. To improve translational relevance, future studies should use the EBI in clinical populations to assess its ability to predict changes in clinically recognised phenomena, such as depressive symptoms and anxiety. The prediction model of changes in well-being predicted only 20% of the variance. However, we do expect this model to perform better in a clinical trial and in a controlled environment. Second, the study has relied on self-reports of drugs, doses and timing, which are not as accurate as in laboratory studies. Psychedelics that are sold in the market are unreliable in many cases and one cannot be sure which drug and what dose was used. Third, there was limited analysis of convergent validity. Although there is clearly some overlap with the MEQ, we are not aware of any other questionnaires that measure a construct closely related to EBI. One way to address this in the future might be to compare EBI scores with quantitative outcomes from qualitative interviews, to assess whether there is some correspondence. A better demonstration of the convergent validity of the EBI will serve to further strengthen its construct validity (Campbell and Fiske, 1959).

In conclusion, EB is an essential component of psychedelic-assisted therapy, and therefore should be measured in future experimental medicine studies and clinical trials with psychedelics, alongside measures of peak and challenging experiences. Quantifying the psychological mechanism of psychedelic-assisted therapy is essential as psychedelic-assisted therapy is rightly both a pharmacological and psychological intervention. The predictive value of peak experiences is well-established within this context, and now the importance of EBs can be better researched and potentially supported as well. Furthermore, based on qualitative studies (Belser *et al.*, 2017; Gasser *et al.*, 2014; Watts *et al.*, 2017) and a broader awareness of the phenomenology of the psychedelic experience, we believe there is scope for additional quantitative measures (e.g. of psychological insight) to be developed, so that a fuller understanding of the psychological and neurobiological mechanism of psychedelic (mind-revealing) therapy can be appreciated and utilised for positive ends.

Introduction

Major depression is among the most common mental health disorders in the United States and carries the heaviest burden of disability among mental and behavioral disorders [1]. Over one third of patients will not achieve remission after initiation of an antidepressant treatment and the likelihood of achieving remission diminishes with subsequent medication trials [2]. These considerations demand exploration of alternative treatment strategies and identification of novel mechanisms that can be exploited to improve outcomes. The finding that glutamate modulators such as ketamine have rapid acting antidepressant effects has expanded the current model of depression beyond the traditional monoamine theory involving serotonin, dopamine and norepinephrine. Recent research has focused on the role of cytokine-mediated inflammation, neurogenesis, and the role of the glutamate in the pathogenesis of depression [3].

The involvement of inflammation in the development of depression has been extensively studied, while that of the fibrinolytic system, which is down-regulated by inflammation in a range of disorders including lung and pleural injury, cardiovascular disease, glomerulonephritis, and cirrhosis [4-6] has been comparatively ignored, even though depression is considered to be an independent risk factor for coronary artery disease that predicts increased morbidity and mortality [7]. Brain derived neurotrophic factor (BDNF), a neurotrophic factor regulated by tissue type plasminogen activator (tPA), has been posited as a key link between stress, cardiovascular disease, and depression as well as its treatment, mainly via tPA-mediated cleavage of BDNF by plasmin [8-10]. Animal models with BDNF Val66Met polymorphisms are associated with decreased BDNF activity and demonstrate increased activation of platelets, alterations in coagulation pathways, changes in vessel wall protein composition and increased depressive phenotype [11]. Here, we review these prior hypotheses and extend them in light of more recent understanding of the role of impaired fibrinolysis, aberrant extravascular fibrin deposition and tissue remodeling that has been the longstanding focus of our group. We also provide new supporting evidence, some from our own laboratory, that newly recognized mechanisms underlying impaired fibrinolysis in the lung and pleural space could occur within the brain parenchyma to promote architectural alterations that lead to the development of depressive symptoms. While psychological explanations for depression are certainly important, our focus in this manuscript is on biologic mechanisms that specifically involve the fibrinolytic system, that could likewise contribute to the pathogenesis of depression and that may be amenable to novel pharmacologic approaches including administration of psychedelic agents.

tPA, urokinase (uPA), plasminogen activator inhibitor 1 (PAI-1), neuroserpin, and urokinase receptor (uPAR) are expressed in the brain in neurons, microglia and astrocytes [12,13] while soluble uPAR (suPAR) is a proteolytic cleavage product that can be detected within the systemic circulation. Interestingly, increased suPAR is a biomarker of depression [12] and potentially suicidality [13]. This supports the concept that abnormalities of the fibrinolytic system occur in depression and could potentially contribute to its pathogenesis (Figure 1). We posit that plasminogen activators, uPAR, and the inhibitors, PAI-1 and neuroserpin, are integral to the pathogenesis of depression, in part by regulating the production of mature BDNF (mBDNF) as well as remodeling of brain architecture, neurotransmission and synaptic plasticity. We also propose that psilocybin, a 5-HT_{2A} serotonin receptor agonist and classic psychedelic can exert anti-depressant effects that are mediated by salutary changes in the fibrinolytic system. The classic psychedelic 5-HT_{2A} receptor agonists, which include d-lysergic acid diethylamide (LSD), mescaline, and *N,N*-dimethyltryptamine (DMT) are capable of inducing robust changes in affect, perception, and cognition. Psilocybin in particular may induce positive psychological experiences of high personal significance leading to enduring beneficial changes in mood, thinking, and behavior [14].

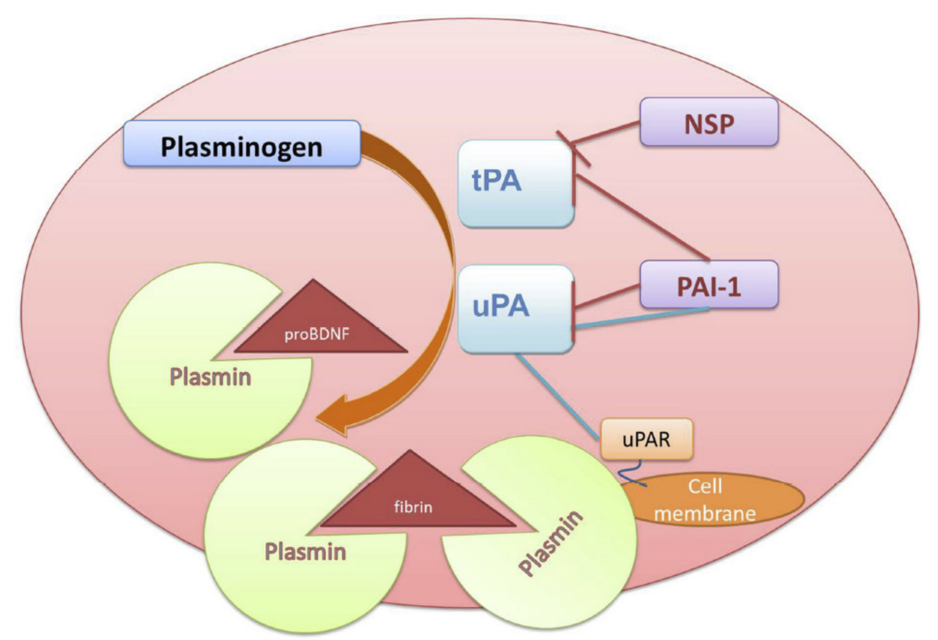

Figure 1. Hypothesis: The contribution of the fibrinolytic system to processing of BDNF as a link to depression. Serpins (PAI-1 and NSP) are elevated in depression and inhibit both tissue (tPA) and urokinase (uPA) plasminogen activators (including uPA bound to its receptor uPAR), suppress activation of plasminogen, and block activation of proBDNF. Inhibition of the fibrinolytic activity promotes transient extravascular fibrin deposition in the brain. An increase in PA activity also results in cleavage of plasminogen producing plasmin, which then activates proBDNF to the activated cleavage product; mature (m)BDNF. However, transient fibrin, due to its high affinity to plasmin and tPA competes with proBDNF for plasmin, and thus affects proBDNF processing.

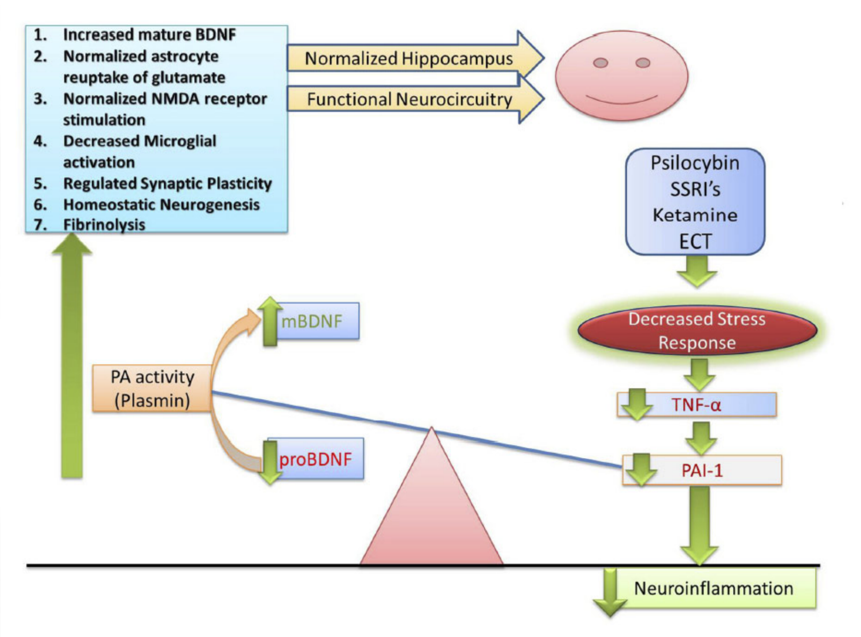
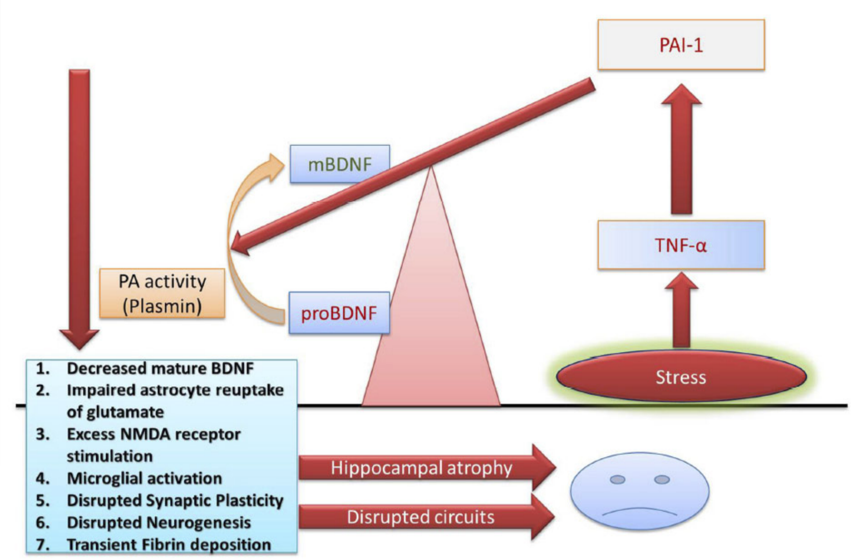
Our overarching hypothesis is that exploration of fibrinolytic system in the brain will provide an avenue for the development of new treatments for depression including administration of psychedelic agents to patients with refractory depression [15]. We specifically propose that serotonergic classic psychedelics such as psilocybin will demonstrate therapeutic effects on the brain including normalization of changes that occur as a result of chronic stress and disruption of the fibrinolytic system through interactions between neuroserpin, tPA and PAI-1 (Figure 2). We infer that psilocybin may decrease PAI1 activity via reduction of TNF-α levels, leading to disinhibition of tPA, increased mBDNF production, normalized synaptic plasticity, and resolution of depression (Figure 3). This hypothesis relies in part on the established link between peripheral and central inflammation in the pathogenesis of depression, which is described in the next section.



1. Increased mature BDNF
2. Normalized astrocyte reuptake of glutamate
3. Normalized NMDA receptor stimulation
4. Decreased Microglial activation
5. Regulated Synaptic Plasticity
6. Homeostatic Neurogenesis
7. Fibrinolysis
Normalized Hippocampus
Functional Neurocircuitry
Psilocybin
SSRI's
Ketamine
ECT
mBDNF
Decreased Stress Response
PA activity (Plasmin)
TNF-α
proBDNF
PAI-1
Neuroinflammation

Figure 2. Proposed effects of dysregulated fibrinolysis on the pathogenesis of depression. Derangements of the fibrinolytic system are integral to the pathogenesis of depression: Stress initiates a cascade in the brain wherein proinflammatory cytokines such as TNF-α increase PAI-1 levels. This inhibits PA activity and blocks plasmin-mediated cleavage of proBDNF to mBDNF. Inhibition of PA activity also promotes transient fibrin deposition. A decrease in mBDNF (and increase in the proBDNF/mBDNF ratio) leads to disruption of hippocampal neurogenesis, synaptic plasticity, and increased hippocampal atrophy resulting in depression.



PAI-1
mBDNF
TNF-α
PA activity (Plasmin)
proBDNF
Stress
1. Decreased mature BDNF
2. Impaired astrocyte reuptake of glutamate
3. Excess NMDA receptor stimulation
4. Microglial activation
5. Disrupted Synaptic Plasticity
6. Disrupted Neurogenesis
7. Transient Fibrin deposition
Hippocampal atrophy
Disrupted circuits

Figure 3. Proposed contribution of the fibrinolytic system to the mitigation of depression by psilocybin and other treatments. Psilocybin, Ketamine, Electroconvulsive therapy and SSRI's may act through antinflammatory, profibrinolytic mechanisms simultaneously decreasing TNF-α and PAI-1 levels thereby increasing PA activity to generate plasmin which cleaves proBDNF to mature; mBDNF. This may lead to restoration of homeostatic functional neurocircuitry, increased hippocampal neurogenesis, and euthymia. Possible delay in activation of proBDNF could occur due to competition for plasmin and tPA with transient extravascular fibrin deposition within the brain parenchyma (Figure 1).

The Linkage Between Peripheral or Cerebral Inflammation and Suppression of the Fibrinolysis in the Brain

Evidence from human studies suggests that increased peripheral cytokine levels are associated with depression and suicidality [16]. A recent meta-analysis indicates that levels of interleukin-6 (IL-6) and TNF-α are significantly higher in depressed patients [17]. Aberrant cytokine elevation profiles have been shown to be potential biomarkers of treatment responses, as a recent study showed that subjects with non-remitted Major Depressive Disorder (MDD) have high baseline levels of TNF-α, which falls with exercise as opposed to antidepressant medications [18]. This study underscores the potential utility of alternative depression strategies or treatments, such as treatment with psilocybin for resistant depression.

Peripheral proinflammatory cytokines may access or directly affect the central nervous system (CNS) through several mechanisms such as activating the vagus nerve, disrupting the blood brain barrier (BBB), or accessing the brain directly via the circumventricular organs or saturable transport systems [19]. The BBB is regulated by several mechanisms involving tPA, which opens the BBB and PAI-1, which tightens the BBB [20]. Overexpression of proinflammatory cytokines in the CNS or in the circulation with induction of a relatively more open BBB, may contribute to neuroinflammation. These and other proinflammatory mediators activate microglia and astrocytes, leading to an enhanced local inflammation and the potential for glial scarification. These processes may suppress normal hippocampal neurogenesis which is associated with depression [21].

Disruption of hippocampal neurogenesis may occur throughout the life cycle as a result of chronic peripheral inflammation due to medical illness [22] or chronic stress [23]. In humans, numerous medical comorbidities including inflammatory bowel disease, diabetes mellitus, and obesity have all been linked to depression and cognitive impairment [24], likely mediated by disruption of hippocampal neurogenesis. These reports suggest a link between chronic inflammation due to co-morbidities with suppression of the fibrinolytic system in the brain.

Synaptic Plasticity, Depression, And The Fibrinolytic System In The Brain

Inflammation, coagulation, and fibrinolysis are intricately interwoven systems that are interactive [4,25]. While inflammation has been intensely studied as a risk factor for depression, the role of the fibrinolytic system in the pathogenesis of this disorder remains poorly understood. Several key elements of the fibrinolytic system linked to synaptic plasticity appear to be altered during stress. For example, uPA and uPAR have been shown to increase cellular viability in the stressed lung epithelium [26] and in lung fibroblasts [27] and we infer that they may similarly do so in the brain. uPA may also promote synaptic plasticity in the brain when upregulated by proinflammatory cytokines involved in depression. tPA and uPA convert plasminogen to its active form plasmin. In the vasculature, plasmin is known to degrade fibrin clots. In the brain, fibrin has been demonstrated to activate microglia, increasing neuroinflammation and potentially depression [28]. While it is currently unclear whether or not transitional fibrin occurs with low grade inflammation in the brain in depression, fibrin possesses high affinity for both tPA [29] and plasmin [30,31]. Its presence in the brain parenchyma could adversely affect neuroplasticity via inhibition of proBDNF activation, thus promoting depression. Moreover, PAI-1, which is upregulated in alveolar epithelial cells during lung inflammation, has been shown to inhibit neutrophil apoptosis and subsequent phagocytosis thereby leading to prolonged inflammation within the injured lung [32]. PAI-1 is primarily located in astrocytes and has been suggested to be antiapoptotic for neurons in the brain [33]. This suggests that both tPA and PAI-1 may be neurotoxic or neurotrophic depending on their relative concentrations. PAI-1 is a biomarker and mediator of poor outcomes in lung and pleural diseases [4,34] and we infer that elevated PAI-1 could likewise be a biomarker of depression (Figures 1 and 2).

While the fibrinolytic system plays a key role in the pathogenesis of renal [35,36], hepatic [37] and acute and chronic lung [4] injuries, this system may be of particular importance in the pathogenesis of depression in patients with lung disease. A recent study has shown that about one in four patients with chronic obstructive pulmonary disease (COPD) have persistent depressive symptoms which are associated with risk of COPD exacerbation and decreased exercise tolerance [38]. Additionally, patients with cystic fibrosis (CF) have been shown to have increased incidence of depression and anxiety [39]. The link between lung illness and depression is becoming better characterized by new research showing the influence of mood on other organ systems and vice versa. Inflammation induced epithelial-mesenchymal transition (EMT) in the lungs is associated with increased expression of epithelial PAI-1 and suppressed uPA and loss of lung function [40].

A process analogous to that which occurs in pulmonary remodeling may occur in the brain as a result of stress-induced inflammation. While fibrinogen, the precursor to fibrin, is not present at extravascular sites within the healthy brain it is elevated in the brains of individuals with schizophrenia [41], multiple sclerosis [42], Alzheimer's disease [43] and normal aging [44], all of which are disorders characterized by neuroinflammation and transient or long lasting BBB disruption [20]. These finding suggest that increased inflammation, decreased fibrinolysis and fibrosis may be involved in the pathogenesis of depression. Transitional fibrin deposition may perpetuate microglial activation, in addition to stress-induced, cytokine mediated microglial activation associated with decreased fibrinolysis, increased neuroinflammation, and depression. uPAR is involved in the recruitment of immune cells and cellular adhesion [45] and is a very sensitive marker of low grade inflammation typically seen in depression [12,13]. Further studies are necessary to characterize the roles of fibrin, tPA, uPA, uPAR, PAI-1 and neuroserpin in regulating stress, neural inflammation and mood (Figure 1 and 2).

In the CNS, tPA has been shown to exert effects that extend beyond traditional fibrinolysis and bridge to the regulation of neural cell functionality and behavior. For example, tPA has been demonstrated to influence synaptic plasticity though several mechanisms including degradation of the extracellular matrix through activation of matrix metalloproteases and interaction with the N-methyl-Daspartate (NMDA) receptor in addition to activation of proBDNF [46,47]. In the brain, tPA has been shown to have a role in memory, learning, and stress dependent behavioral responses [48]. In addition to its role in learning, tPA through NMDA receptor mediated activity, has been shown to be involved in the development of the fear response to acute stress through regulation of plasticity in the hippocampus [49]. While the administration of tPA itself for treatment of depression carries the risk of intracerebral bleeding and potentially neurotoxicity in the ischemic brain [50], the up-regulation of endogenous tPA activity is in principal an approach that could be pursued for the treatment of depression.

The literature also provides a link between the fibrinolytic system in the brain, BDNF and depression. BDNF is synthesized in cell bodies of neurons and glia and is transported to terminals where it is released [51]. It has been demonstrated to play a pivotal role in neurogenesis and depression. proBDNF and mBDNF have been shown to have opposite effects on neurogenesis and accordingly patients with major depression demonstrate elevated levels of proBDNF and decreased levels of mBDNF [52]. proBDNF induces dendritic retraction and apoptosis and long-term depression, while mBDNF promotes dendritic growth, cell survival, and long term potentiation indicating the importance of appropriate levels of functional tPA or perhaps uPA. A recent study demonstrated that an enriched environment increases tPA-dependent plasmin cleavage of proBDNF in mice [46]. Exercise has also been shown to increase mBDNF and tPA levels in humans which correlates with euthymia [53]. In rats, electro convulsive therapy, a rapid acting neuromodulatory treatment that is the gold standard treatment for resistant depression, has been shown to increase mBDNF and tPA levels [54], unlike imipramine, suggesting a novel tPA-mediated regulatory mechanism of action.

In the normal brain with no infiltrating microglia, PAI-1 is minimally expressed, and biochemical evidence showing strong inhibition of tPA suggests that the primary inhibitor of tPA is likely neuroserpin [55], particularly as overexpression of neuroserpin decreases activity levels of tPA [56]. Neuroserpin and tPA are expressed in neurons throughout the developing and adult nervous system [47]. Both overexpression and knockout of neuroserpin lead to increased anxiety like responses in mice, further supporting the role of the fibrinolytic system in regulating mood [57].

The literature suggests that tPA is a gliotransmitter mediating cross talk between neurons and astrocytes [58]. Astrocytes regulate the effective concentration of extracellular tPA and glutamate, influencing NMDA receptor signaling involved in regulation of mood. During chronic stress, excess hypothalamic-pituitary-adrenal (HPA) activation leads to activation ot microglia and impaired astrocyte reuptake of glutamate leading to excess extracellular NMDA receptor stimulation, neuro-inflammation and subsequent depression [59]. The disruption of the homeostatic balance of available extrasynaptic tPA, which is regulated by neuroserpin and astrocyte reuptake of glutamate, appears to be critical to cell survival and limitation of neuroinflammation.

uPA may be involved in the regulation of mood as well. Both tPA and uPA activate plasminogen to plasmin leading to degradation of extracellular matrix, which is critical to axonal and synaptic plasticity. Mice deficient in uPAR exhibit increased anxiety and reduced social behavior [60] and cognitive impairment [61], a finding that lends strength to our postulate that this receptor, through localization of uPA within brain cells, also contributes to regulation of cleavage of BDNF and alleviation of depressive symptoms. Notably, uPA-/ - mice have been demonstrated to exhibit a clear reduction in exploratory activity, an enhanced fear response to tone [62] and increased neuroinflammation [63].

Antidepressants, Ketamine and Psilocybin: Established and Hypothetical Effects on the Brain Fibrinolytic System and Depression

Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, sertraline, and citalopram inhibit the serotonin transporter (SERT, SCC6A4), a plasma membrane integral glycoprotein found in neurons and platelets that regulates reuptake of serotonin across the plasma membrane. Inhibition of SERT leaves more serotonin available in the synaptic cleft to increase serotonergic neurotransmission, one of the putative mechanisms of SSRIs. SSRIs have been shown to have significant efficacy in severe depression [64]. However, these drugs exert various side effects such as akathisia, sexual dysfunction and weight gain that may lead to discontinuation [65]. Furthermore, SSRIs may take up to 3-4 weeks to take effect, during which time the medication may be discontinued prior to titration to the optimal dose.

Neural circuits involved in emotional processing and reward seeking have been demonstrated to be dysfunctional in major depressive disorder. Individuals with major depressive disorder have demonstrated decreased resting state functional connectivity (RSFC) among specific circuits in the affective network involved in emotional processing and increased RSFC among default mode network neural circuits involved in self referential processing [66]. These imaging studies suggest electrophysiologic circuits that could be interrogated to see if these areas are functionally altered by disruptions of fibrinolysis or transient fibrin deposition in the depressed brain (Figure 1 and 2). Interestingly, psilocybin and mindfulness meditation has been shown to decrease activity in the default mode network [15,67] which could be therapeutic in depression by decreasing rumination or negative self-referencing contributing to the stress response, neuroinflammation and decreased fibrinolysis associated with depression.

Depressive derangements of the hippocampus have also been associated with altered functionality of the fibrinolytic system in the brain (Figure 2). In rats, sertraline (Zoloft), a selective SSRI, has been shown to increase the expression of tPA in the hippocampus and reverse depressive behavioral change in rats exposed to five weeks of chronic unpredictable mild stress [68]. In the same study, sertraline increased BDNF levels in the prefrontal cortex and hippocampus.

There is a growing body of additional clinical evidence supporting the hypothesis that the activity of the fibrinolytic system is decreased in depression. A study of women with MDD on anti-depressant therapy showed elevated plasma PAI-1 associated with increased abdominal fat compared with controls [69]. Variants of the SERPINE1 gene that encodes PAI-1 have been demonstrated to predict response to SSRI's in adults with MDD [70] and in individuals with Alzheimer's disease (AD) and depression [71]. These findings indicate that AD and MDD may show overlapping pathophysiology regulated by derangements in fibrinolysis, potentially alleviated by psilocybin.

Blockade of serotonin uptake in platelets by SSRIs could decrease associated PAI-1 release and its subsequent activity in the blood and brain, in effect elevating Plasminogen Activator (PA) activity leading to higher plasmin levels with cleavage of proBDNF to mBDNF (Figures 2 and 3). Increased mBDNF promotes hippocampal neurogenesis and resolution of depressive symptoms associated with chronic stress induced hypersecretion of cortisol and adrenaline. Whether SSRIs regulate PAI-1 in the systemic circulation in patients receiving these drugs and how cardiovascular risk is affected with chronic use of these drugs is currently unclear.

Ketamine, an NMDA receptor antagonist and fast acting antidepressant has been shown to modulate the inflammation mediated kynurenine pathway with treatment response predicted by baseline levels of IL-6 [72]. To our knowledge, the effect of ketamine on PAI-1 expression within the brain has not been evaluated. Because PAI-1 can revert to an irreversibly latent form or can be cleaved with loss of inhibitory activity, the processing of PAI-1 in response to exposure to ketamine and other drugs and how it is processed in depression itself are issues that are germane to the better understanding of the pathogenesis of this condition. It is possible that by decreasing TNF-α and other pro-inflammatory cytokine activity, ketamine may indirectly affect PAI-1 levels, fibrin deposition, and increases of PA activity involved in hippocampal neurogenesis and the pathogenesis of depression.

Psilocybin binds with high affinity to the 5-HT_{1A}, 5-$HT_{2A/C}$, 5-HT_6 and 5-HT_7 subtypes of the serotonin receptors [73]. Psilocybin and other serotonergic classic psychedelics have been shown to exert their effects through agonism at the 5-HT_{2A} subtype of the serotonin receptor [74], which is associated not only with psilocybin's psychedelic effects, but also with vascular smooth muscle contraction, platelet aggregation, thrombus formation, and coronary artery spasm [75]. The psychedelic effects of psilocybin include perceptual changes, labile moods vacillating from joy to anxiety, and cognitive changes including sense of meaning, insight or ideas of reference. The mystical experience, as defined by Roland Griffiths at Johns Hopkins, induced by psilocybin, is defined by abstract traits such as transcendence of time/space, unitary being, sense of sacredness, and ineffability. Researchers at Johns Hopkins have demonstrated that these traits of psilocybin experiences can be quantified by questionnaires that assess the occurrence of the mystical experience after psilocybin administration, the presence of which can be correlated with enduring positive attitudes, mood and behavior after psilocybin administration [14].

Recent studies suggest that 5-HT_{2A} receptor modulation may have therapeutic potential in treating depression. Downregulation of 5-HT_{2A} receptors, which may occur in response to 5-HT_{2A} receptor stimulation, mediates antidepressant and antianxiety effects of antidepressants and atypical antipsychotic drugs [76]. Studies have shown that cortical 5-HT_{2A} receptor expression is increased in postmortem samples of depressed and suicidal patients [77, 78]. It is possible that the region-specific up regulation of 5-HT_{2A} receptors associated with mood disorders and borderline personality disorder [79] may occur in response to stress related decreases in serotonin transmission, and that these receptors may subsequently be regulated to salutary levels in response to increased 5-HT_{2A} stimulation associated with psychedelic use.

It appears that the 5-HT_{2A} receptor upregulation is linked to the response to inflammation and fibrinolysis as well. C57BL/6J mice have varying degrees of psychological resiliency when exposed to chronic stress, with some mice manifesting behavioral symptoms of depression such as floating in the forced swim test and hyperactivity under stressful lighting conditions. Mice that manifest depressive symptoms demonstrate elevated TNF-α and SERT in the pre-frontal area, while all chronically stressed animals, resilient or susceptible, showed enhanced expression of 5-HT_{2A} and Cox-1 in the pre-frontal area. The study suggests a unique, direct correlation between TNF-α levels, neuroinflammation and expression of 5-HT_{2A} receptors. Previous studies in rabbits demonstrated that 5-HT_{2A} agonists such as LSD can significantly reduce cortical 5-HT_{2A} expression by 33-66% within days [80]. Of note, it has already been established that TNF-α and PAI-1 levels are directly correlated, suggesting that psilocybin could restore the 5-HT_{2A} receptor to pre-stress levels with concomitant and potentially critical salutary downregulation of PAI-1 or perhaps neuroserpin.

R-DOI, a potent psychedelic and 5-HT_{2A} agonist has been demonstrated to have potent anti-inflammatory effects. R-DOI is noteworthy for its specificity to the 5-HT_{2A} receptor which differentiates it from psilocybin. Studies show that R-DOI can block progression of a mouse model of asthma [81], possibly via blockade of TNF-α signaling, which could lead to reduction in PAI-1 levels and alleviation of depressive symptoms. There is also evidence that demonstrates that the microglial 5-HT_{2A} receptor may regulate the release of microglial vesicles called exosomes that may contain cytokines involved in neuroinflammation and growth factors involved in neurogenesis [82]. It is plausible that 5-HT_{2A} agonism may regulate the stress response at the level of the microglia via regulation of exosomal cytokines and growth factors necessary for neuronal growth and survival.

Emerging evidence supports the idea that psilocybin may exert effects through the limbic system including the hippocampus and amygdala that are involved in emotional processing. Psilocybin has been shown to normalize limbic hyperactivity in individuals with depressed mood by attenuating amygdala hyperactivity and increasing positive affect [83]. In mice, low dose psilocybin has been demonstrated to rapidly extinguish cued fear conditioning and induce a slight non-significant trend toward increased hippocampal neurogenesis, suggesting a potential role in the treatment of Post-Traumatic Stress Disorder (PTSD) [84] and possibly depression. Psilocybin has also been shown to be well-tolerated in humans in a controlled setting with proper supervision, screening and preparation [14] and may lead to increases in the personality domain of openness in healthy adults [85]. Small pilot studies in humans have shown efficacy of psilocybin in the treatment of anxiety in advanced stage cancer [86], as well as tobacco [87] and alcohol addiction [88]. Analysis of data from the National Survey of Drug Use and Health pooled across 2008-2012 by Hendricks *et al*. [89] demonstrated that psilocybin may be protective in patients with psychological distress and suicidality. Recently, a clinical study has demonstrated that psilocybin may reduce high sensitivity to social rejection that is characteristic of depression, suggesting that this drug is useful in reducing predisposing factors to depression [90]. Another small recent pilot study suggests that psilocybin administration with psychological support is a safe, efficacious treatment for refractory depression [91].

The role of ketamine and psilocybin in the regulation of the fibrinolytic system in the brain has not yet to our knowledge been studied. However, previous studies of the 5-HT$_{2A}$ receptor suggest a possible therapeutic role for psilocybin in depression involving the fibrinolytic system. Hypertrophic adipocytes have been shown to upregulate expression of the 5-HT$_{2A}$ receptor and PAI-1, while suppression of 5-HT$_{2A}$ gene expression enhances adiponectin expression, which is involved in regulation of glucose levels as well as fatty acid breakdown and is normally downregulated in obesity [92]. This finding demonstrates that downregulation of the 5-HT$_{2A}$ receptor by psilocybin could be associated with reduced PAI-1 expression and potentially help with weight loss and depression simultaneously. PAI-1 is deleteriously up-regulated in both conditions. Whether 5-HT$_{2A}$ receptor modulation and PAI-1 upregulation predispose to depression through interactions with components of the fibrinolytic system remains to be determined.

The role of psilocybin in the treatment of depression remains to be delineated. However, we posit that its administration is beneficial in reducing neuroinflammation, and restoring the fibrinolytic system to baseline, a postulate that can be tested in wild type mice with depressive behavior. If we are correct that effective therapy for depression is unified around a restoration of tPA leading to plasmin mediated activation of BDNF, preservation of neurogenesis and synaptic plasticity and that psilocybin reverses downregulation of tPA activity, the postulate can be confirmed. Additionally, the importance of changes in key components of the fibrinolytic system; tPA, uPA, uPAR or PAI-1 to depressive phenotype can be tested in knockout mice or in animals deficient in plasminogen and exposed to depressive stimuli. Transgenic mice that have upregulation of PAI-1 are also available to determine how its overexpression affects depressive symptoms.

Through *in vitro* studies with astrocytes involving the assessment of the effect of inflammatory cytokines such as TGF-β and TNF-α on the fibrinolytic system, we can assess the potential of psilocybin to alleviate pro-inflammatory, anti-fibrinolytic changes induced in glial cells. Clinically, we are assessing the role of mindfulness meditation on inflammatory and fibrinolytic biomarkers in depression. These studies may add support to pursuing further clinical trials using psilocybin for treatment resistant depression.

In conclusion, the preponderance of literature suggests that the pathogenesis of depression involves dysregulation of the fibrinolytic system and that antidepressants in common use and treatment candidates could be involved in their regulation. We specifically hypothesize that the fibrinolytic system exerts potentially critical effects in the pathogenesis of depression and that psychedelics such as psilocybin may regulate the fibrinolytic system in a salutary manner. We further posit that the therapeutic effects of psilocybin and perhaps commonly used antidepressants act as anti-inflammatory, profibrinolytic treatments that reduces neuroinflammation engendered by chronic stress. Increased inflammation through TNF-α and likely other proinflammatory mediators expressed in the brain is associated with elevated PAI-1 levels, increased 5-HT$_{2A}$ cortical expression, and decreased tPA activity in the CNS. These alterations disrupt synaptic plasticity in structures that mediate functional brain circuits involved in mood. We hypothesize that psilocybin exerts an antidepressant effect by reducing PAI-1 levels, decreases neuro-inflammation and fibrin deposition in the brain and restores the 5-HT$_{2A}$ receptor to pre-stress levels leading to normalized serotonergic tone associated with euthymic mood. Psychedelics have been historically stigmatized, and are currently schedule 1 substances in the U.S. making initiation of new research into the treatment of resistant depression with psilocybin a challenging endeavor. Despite these challenges, we believe that it is imperative to leave no stone unturned when alleviation of chronic suffering from depression is a potential outcome.

Abstract

How profoundly can humans change their own minds? In this paper we offer a unifying account of meditation under the predictive processing view of living organisms. We start from relatively simple axioms. First, the brain is an organ that serves to predict based on past experience, both phylogenetic and ontogenetic. Second, meditation serves to bring one closer to the here and now by disengaging from anticipatory processes. We propose that practicing meditation therefore gradually reduces predictive processing, in particular counterfactual cognition - the tendency to construct abstract and temporally deep representations - until all conceptual processing falls away. Our *Many-to-One* account also places three main styles of meditation (focused attention, open monitoring, and non-dual meditation) on a single continuum, where each technique progressively relinquishes increasingly engrained habits of prediction, including the self. This deconstruction can also make the above processes available to introspection, permitting certain insights into one's mind. Our review suggests that our framework is consistent with the current state of empirical and (neuro)phenomenological evidence in contemplative science, and is ultimately illuminating about the plasticity of the predictive mind. It also serves to highlight that contemplative science can fruitfully go beyond cognitive enhancement, attention, and emotion regulation, to its more traditional goal of removing past conditioning and creating conditions for potentially profound insights. Experimental rigor, neurophenomenology, and no-report paradigms combined with neuroimaging are needed to further our understanding of how different styles of meditation affect predictive processing and the self, and the plasticity of the predictive mind more generally.

1. Introduction

We typically experience ourselves as if in an objective world in which time, space, and self are fixed properties. However, severe psychopathology, brain trauma, psychoactive compounds, and virtual reality environments demonstrate that the way the brain constructs experiences is not set in stone. In certain circumstances, it is possible to lose control of one's body, to forget one's own name, to perceive something that is not there, and to believe one's mind is being controlled by an external force. Our sense of self is also subject to change. It is possible to dissociate, to experience depersonalization, and even to believe that one is already dead. Transformations of experience can be externally induced, but they can also be generated from within.

One way that experience can change from within is through intensive mental training, as cultivated by meditation. Thousands of meditation practitioners going back at least three millennia have reported accessing states far outside the ordinary mind. Meditators, even in laboratory settings corroborated by neural activity (Dor-Ziderman *et al*., 2016), report that aspects of experience that we often take to be stable and unchanging, such as time, space, and self, can in fact be modulated. Moreover, according to many of these meditation traditions attaining such changes in experience are desirable and permit one to lead a happier and more compassionate life. Mindfulness meditation-based interventions are now a conventional treatment for mental health in some countries (Rycroft-Malone *et al*., 2017) and downloads of mindfulness apps are well into the tens of millions. The scientific study of meditation is also growing exponentially (Van Dam *et al*., 2018). But as yet, there does not exist a unifying account of how meditation generates its manifold empirical and phenomenological effects. The lack of a general theory of meditation may be partly owing to a lack of a unifying scientific account of the mind, brain, and behavior, which has been missing until relatively recently.

Beginning with the simple axiom that an organism must resist entropy and the dissolution of its boundaries, Karl Friston's Free Energy Principle (2010) and predictive processing more broadly, is gaining scientific traction as an all-encompassing account of living organisms. It recharacterizes organisms as fundamentally anticipatory - as continuously inferring or predicting the outside world based on prior experience. This framework supposes to explain everything from the behavior and computations of unicellular organisms to the complex cognitive and emotional inner landscapes of homo sapiens through one and the same mechanism: free energy minimization. Due to the fact that the brain lacks direct access to the external world, it must 'guess' the causes of sensory experience based on past experience in order to adaptively interact with it. To improve its guesses, the brain is proposed to *minimize the difference* between these 'guesses' and external input (i.e., free energy or prediction error). Prediction error minimization is proposed to operate at all levels of the neural hierarchy, including those detached from the present environment in service of future adaptive behavior. Thus, in this framework, perception, action and everything in between, are constructed through predictive models that have previously come to reliably reduce *errors* in prediction. Therefore, past experience is a pervasive factor underlying all mental activity.

Obviously, having a mind that is constructed through past experiences is advantageous in many situations. Yet, a mind that is too restricted - that too often occupies habitual modes of thinking and feeling - and is not flexibly adapted to changing situations, can be maladaptive. Crucially, within the free energy framework, the brain does not simply undergo influences from the *outside*, but continuously generates its own model of the environment from *within* based on past experience, a reality that is continuously tested against the outside world. This also turns the typical notion of brain plasticity - the capacity to undergo change (Buonomano & Merzenich, 1998; Feldman, 2009) - on its head (Boonstra & Slagter, 2019). That is, plasticity is not simply the result of outside influences (or the capacity to *receive* form), but very much about the capacity to *produce* form from *within* (Boonstra & Slagter, 2019). This raises important questions about the plasticity of the predictive mind. If our inner mental landscape is determined by models that through past experience have come to reliably minimize uncertainty, to what extent are these models still plastic or capable of revision based on new experiences? And what may be fruitful ways to promote such plasticity given their internal construction?

In this paper, we argue that this new understanding of the brain as a predictive organ coincides well with meditation, which in some cases explicitly aims at deconstructing the mind from within, in order to allow one to experience things anew, no longer wholly determined by acquired mental habits (Friston *et al.*, 2017). Therefore, here we aim to, 1) provide a unifying account of empirical and phenomenological effects of intensive meditation practice that is grounded in predictive processing, and 2) to demonstrate how scientific research on meditation can reveal novel insights into the plasticity of the predictive mind.

The essence of our theory is quite simple. Our main contention is that meditation gradually brings the practitioner more and more into the present moment, thereby progressively abating hierarchically (i.e., temporally) deep predictive processing in the brain. We contend that this not only reduces temporally extended processes, such as episodic future thinking and decision making, but can also explain more unusual kinds of experiences reported by meditators, including loss of self-other distinction and the cessation of time as in non-dual awareness (Josipovic, 2010; Lindahl & Britton, 2019). That is, if awareness rests in the here and now, all mental processes that involve abstract and temporally deep processing should logically fall away, including sense of agency, time, space, and body representation. Even seemingly direct experiences, like that of a flower or a teacup, demand a complex process of construction from past experience and include anticipation of possible changes in sensory input (e.g., proprioceptive and sensory changes related to drinking from the cup). Thus, if awareness rests in the here and now, all conceptualization should also dissipate.

This paper is organized in the following way: we will begin with an outline of predictive processing and its key components, including views on the nature of self, insight, and fact free learning (Friston, 2018; Friston *et al.*, 2017). We then introduce three well-delineated meditation practices, known as focused attention (FA), open monitoring (OM), and non-dual (ND) meditation (Josipovic, 2010; Lutz *et al.*, 2008b, 2015a). We focus on these meditation techniques for the sake of scope, but also because our account makes the novel neurobiologically informed proposal that there is a single mechanism which puts each of these practices clearly on a continuum. That is, *each practice gradually reduces temporally deep processing in the brain*. We will then reformulate the different meditation techniques, and associated changes in phenomenology, and key neural and cognitive effects of meditation in terms of our model. This will cast some seminal findings in a new light, as we also discuss. Finally, we will make several testable predictions that derive from our novel account and outline important avenues for future research. For example, we make state-specific and technique-specific predictions about how meditation may affect habitual responding, learning, and self-specific processing. This capacity to restructure deeply engrained mental habits is what makes meditation a valuable tool for investigating the plasticity and nature of the predictive mind.

For our theory, we have chosen the name *many-to-one* to depict the reduction in *counterfactual or temporal depth*[1] (Corcoran *et al.*, 2019) - the tendency to abstract away from the present moment (Gilead *et al.*, 2019) - that occurs during meditation. There is widespread agreement that information is represented hierarchically in the brain, with early layers of the hierarchy being more temporally precise and concrete, and higher layers being more temporally thick and abstract (Friston, 2008; Huntenburg *et al.*, 2018). The quintessence of meditation is also being in the present moment. Thus, as a heuristic version of our model, we suggest that meditation reins in the mind's habitual tendency to abstract (*the many*) away from the here and now until all phenomenological distinctions stop (*the one*[2]). Metaphorically, we suggest that meditation *prunes*[3] *the counterfactual tree* (see Figure 1).

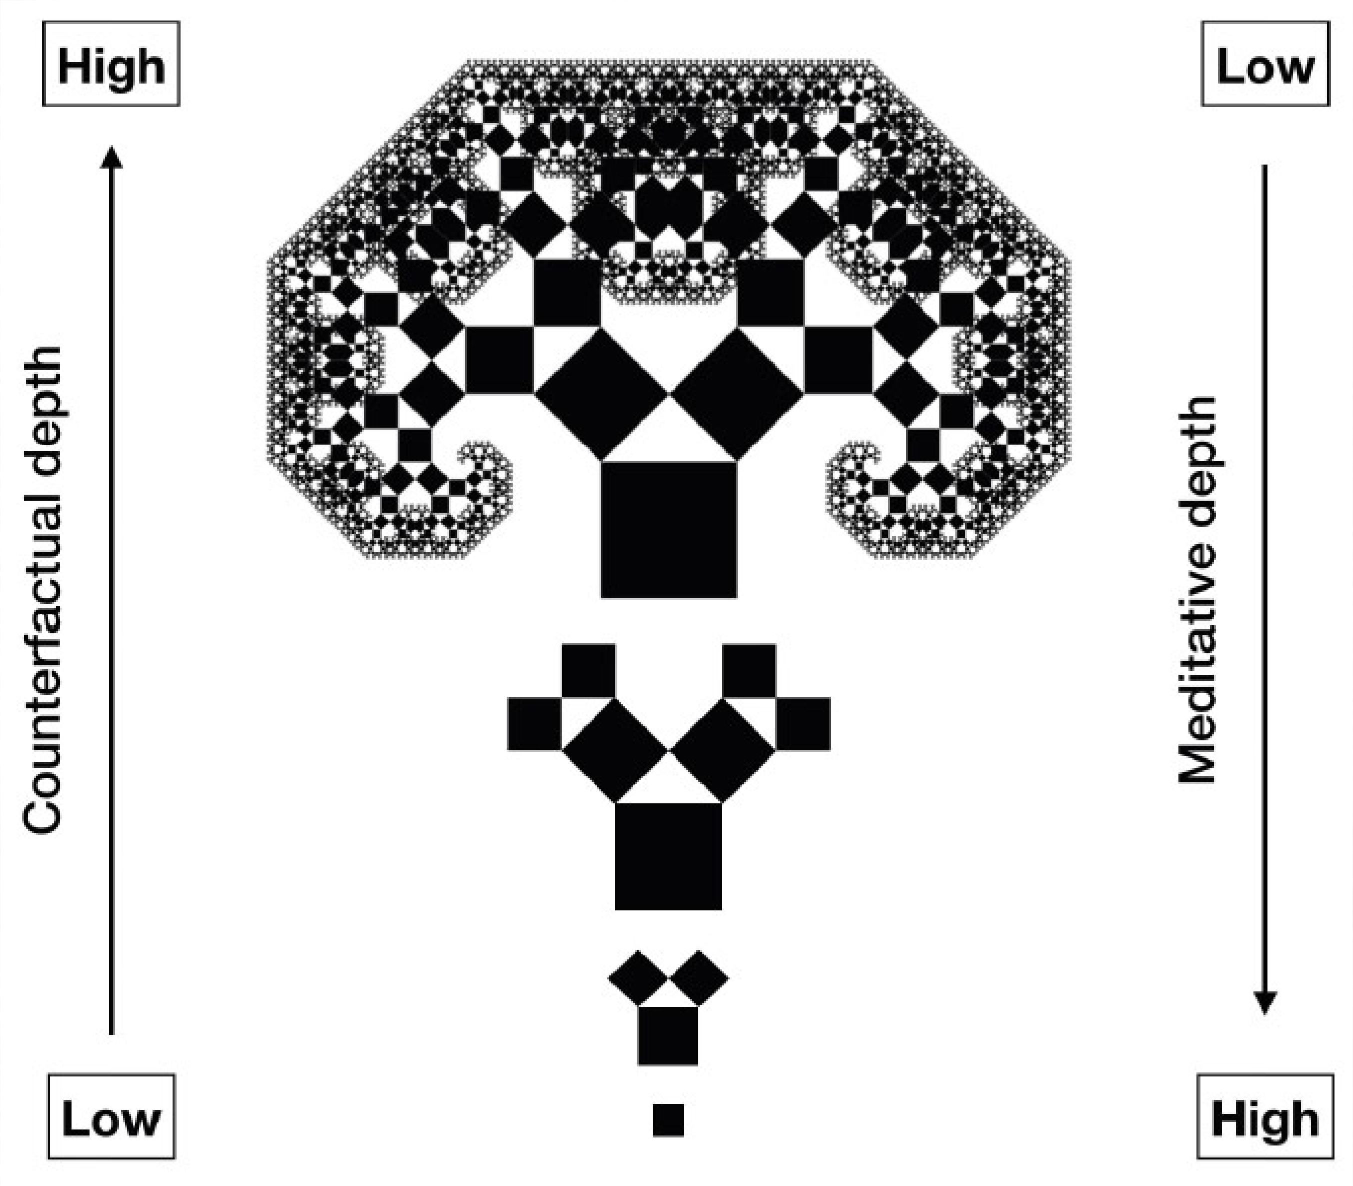

Figure 1. Here we use the Pythagoras Tree to provide an intuitive illustration of how organisms represent the world with increasing counterfactual depth or abstraction[4]. The tree is constructed using squares that are scaled down by √2/2 and placed such that the corners of the squares meet and form a triangle between them, recursively. Analogously, the brain constructs experience from temporally precise and unimodal models of present-moment sensory input (e.g., pixels on a screen), into ever more abstract, transmodal, and temporally deep models (e.g., a theory paper). Meditation brings one increasingly into the present moment, thus reducing the tendency to conceptualize away from the here and now, akin to observing the pixels rather than the words.

According to the predictive processing framework, the self is also a model constructed in the brain's predictive hierarchy. Thus, pruning the counterfactual tree would also logically engender changes in one's sense of self. Indeed, the traditional roots of many meditation techniques (such as Buddhism) explicitly aim to provoke changes in the self (Dahl *et al.*, 2015). Consistent with this praxis, we will also propose that the three meditation techniques gradually deconstruct increasingly foundational forms of self-representation, beginning with the narrative self (Gallagher, 2000), and then the embodied self (Blanke & Metzinger, 2009; Seth, 2013), and finally dissolving the very foundation of a subject-object distinction (Josipovic, 2014). Moreover, we argue that reducing temporally deep processing allows certain insights to arise as the constructed nature of cognition becomes perceptible. Finally, as an interesting counter-model, we compare our account of meditation to a popular predictive processing account of psychedelics (Carhart-Harris & Friston, 2019).

2. Predictive Processing

What does the brain do? What is the basic imperative of a living organism? Evolution and gene selection theory were able to provide answers to core questions at the level of biology, explaining how life can emerge and adapt over time through natural selection (Ashburner *et al*., 2000). However, a unifying account of life *within the living* has yet to take hold. Organisms in their relatively short life spans also change, adapt, behave, think, and feel and seem to possess some inner imperative to survive beyond procreation. What is at the heart of this compulsion? According to the free energy principle (Friston, 2010), the basic imperative is not pleasure seeking, or any kind of simple reinforcement scheme. The imperative is to maintain a boundary between oneself and the world, or in other words, to resist the second law of thermodynamics (i.e., the tendency for isolated systems, including the human organism, to become more entropic over time). If an organism loses its boundaries, it becomes more entropic as its constitution and the world become increasingly inseparable. In order to avoid the dissolution of its boundaries, what the organism *does* is make predictions across many timescales to produce autopoietic[5] actions that minimize the tendency towards entropy (Friston & Buzsáki, 2016). It is perhaps these relatively uncontroversial axioms on which the free energy principle is founded that has made it so appealing to philosophers and scientists alike (Allen & Friston, 2018; Clark, 2013; Milliere & Metzinger, 2020; Wacongne *et al*., 2011).

The organism's survival depends on high fidelity predictions. But how can the organism and its brain, which has no direct access to the outside world - only to the often ambiguous and noisy sensory signals it receives via the senses - improve its predictions? In vision, for example, the size of the image on the retina is influenced by the size of the object and how far it is from the observer. The computationally efficient solution to this problem is for the brain to prune its models using *prediction errors*. By processing the difference between model predictions and sensory input the organism can indirectly quantify the accuracy of its predictions to improve the models that generated them (Friston, 2010). Focusing on minimizing prediction errors (*entropy in the long-term*) is computationally much less expensive than processing a complex temporally layered gamut of interoceptive and exteroceptive input in every instance.

To illustrate how predictive processing works, consider the following example of drinking water. Picking up a glass of water, while avoiding tipping over the dishwashing detergent, and drinking the water, entails successful modelling of one's body, movements, immediate visuo-spatial environment, as well as the internal mechanisms that prevent the water from entering the trachea. Moreover, if one is subsequently "surprised" by the sensory input (e.g., what is meant to be water), then it is likely that one is drinking something dangerous. Indeed, the very desire to drink fluids is itself a prediction error arising from appropriate expectations of one's bodily volume of water via osmolality. It is not difficult to see then that an organism that does not aim to minimize prediction errors over time would not survive for long.

In order to keep our discussion focused, below we review five core features of predictive processing that are relevant in the context of meditation. The first is the *hierarchical* nature of predictive processing, which is important because our model proposes that meditation gradually reduces the temporal depth of hierarchical processing. The second is *active inference* which accounts for action (mental and physical), and is relevant because meditation often involves either complete non-action such as sitting still, or a highly constrained action like walking slowly. Mental actions are also often constrained (e.g., thoughts) by focusing attention on a sensation such as the breath (Lutz *et al*., 2019). The third is *precision-weighting*, which is equated with attention in the predictive processing framework (Friston & Stephan, 2007; Hohwy, 2013). Precision-weighting is also highly relevant because changes in the deployment of attention are important in many meditation techniques (Slagter *et al*., 2011) and ordinary attention is to be released altogether in some meditation practices. And the fourth is the implication that self consciousness implies minimizing *expected* free-energy in next moments in time (Friston, 2018). As stated above, the nature of self is important because many meditation techniques explicitly aim to engender changes to one's sense of self (Dahl *et al*., 2015; Dor-Ziderman *et al*., 2016). Finally, we describe how the brain can learn without sampling new input - e.g., as in meditation - by refining, selecting, and compressing existing representations, through *fact-free learning* (Friston *et al*., 2017). Learning and attaining 'insights' about the nature of one's mind are also at the heart of many meditation practices (Bodhi, 2011), and we suggest that these may naturally arise through fact-free learning[6].

2.1 A hierarchy of expectations

It is a key tenet of the free energy principle that the brain models the world hierarchically (Friston & Stephan, 2007). Early basal layers of processing are temporally precise and concrete (e.g., sensory and interoceptive input) and deeper layers are temporally thick and abstract (e.g., thoughts and concepts, Limanowski & Friston, 2020). Each layer of the hierarchy aims to predict the input of the layer below, and inconsistencies between predictions and the input (i.e., prediction errors) are propagated further up the hierarchy. The hierarchical nature of the brain is not controversial (Badcock *et al.*, 2019; Friston, 2008; Huntenburg *et al.*, 2018; Kumar *et al.*, 2007; Lee & Mumford, 2003; Taylor *et al.*, 2015; Vidaurre *et al.*, 2017). We will unpack the nature of this hierarchy and how it relates to self-processing and meditation in later sections.

Predictive processing accounts such as Friston's free-energy principle have roots in Bayesian Brain theories. That is, in order to answer the difficult question of, "how should I update my beliefs given new evidence" the brain is proposed to follow hierarchical *Bayesian* inference. This means that the brain computes the 'new hypothesis' (*posterior* probability) by considering the 'old hypothesis' (*prior* probability) and the *likelihood* of the new evidence given the 'old hypothesis' or prior. Clearly, in this scheme priors - intuitively analogous to beliefs - play a key role in what the organism ends up experiencing and believing, at every layer of the hierarchy. These priors are conditioned by past experience, and not just developmentally but also phylogenetically (Badcock *et al.*, 2019). Thus, some priors may be deeply resistant to change (i.e., *stubborn*). Examples of stubborn predictions are expectations that critical physiological variables are within some range (e.g., a bodily temperature of ~37 degrees Celsius), the expectation that one has a body, and the expectation that light comes from above (Yon *et al.*, 2019). Predictions established ontogenetically are conceivably less stubborn than predictions that are necessary for survival and developed phylogenetically, but an important outstanding question is to what extent these predictions once established, e.g., after sensitive periods in development, can still be modified based on new experiences and learning (Yon *et al.*, 2019).

2.2 Perceptual and active inference

Prediction errors can be minimized in two ways: an organism can change its models, or it can *act in ways that are consistent with expectations*. Put differently, one can revise (perceptual inference) or confirm (active inference): like a scientist who either changes their theory in light of new evidence, or turns a blind eye, and instead conducts experiments (makes actions) that produce expected results (Friston & Frith, 2015). Under this account, actions are reflex arcs that unfold to create an experience that is consistent with an expected state of sensory affairs (Allen & Friston, 2018). Returning to our earlier example, organisms have certain stubborn expectations regarding fluid levels. If those expectations are not met, a strong prediction error is incurred in the form of thirst. Once a certain threshold is reached, the organism generates a prediction regarding a series of sensory and proprioceptive states that eventuate in an appropriate fluid to weight ratio. By reducing the difference (prediction error) between this prediction and the current sensory input, the organism will find water and regain its balance. Like the imperative to stay hydrated, modeling of the world is primarily in the service of *utility* rather than fidelity: "The brain is in the game of predicting the world, but only as a means to the end of embodied self-preservation" (Allen & Friston, 2018, p. 12).

It should be noted that active inference, although directed at confirming predictions, is also critical for model revision because by manipulating the sensory input through action, the brain can also test hypotheses in order to check them against the subsequent input. In other words, by generating information through action, the brain can test its models about the outside world. Crucially, the hierarchical and temporally deep nature of generative models in the human brain permits that we can also *think about actions and their potential consequences without performing them* (Friston, 2018). Thinking, decision-making, and guided attention are thus kinds of mental actions (Metzinger, 2017; Spratling, 2016). They allow us to disembody from the present moment flow of sensory data in order to covertly entertain possible, but nonexistent states, i.e., *counterfactual hypotheses* (Metzinger, 2017). This counterfactual cognition is thought to be in the service of allostasis - of predicting future states that minimize expected free-energy under different scenarios (Corcoran *et al.*, 2019). And since all predictive processes are driven by past experiences, then higher cognition is similarly conditioned by past mental experiences. That is, learning is also a pervasive feature of thought.

2.3 Attention

Simply revising beliefs whenever prediction errors occur is ultimately not beneficial, as incoming signals are often unreliable or noisy or not representative of the larger world. Hence, the reliability or *precision of prediction errors* ought to also play a role. That is, not only the upcoming sensory input needs to be estimated, but also its precision (second order prediction), which requires integrating information over time (Friston, 2009). In predictive processing, attention is equated with *precision-weighting* and plays a key role in contextualising prediction errors (Feldman & Friston, 2010). Intuitively, attention partly determines whether one changes their beliefs (priors) in light of new information. The quintessential example is that of perception in either dark or well-lit contexts. In the dark, visual input tends to be awash with inconsistency and low definition, and thus prediction errors have *low precision* and are more likely to be ignored. On the other hand, in daylight the sensory input is clear and reliable, and thus even a surprising visual event will be registered because it has *high precision*. And paying attention to a blurry object in our periphery (is it a teacup or a mug?) can incur more *precision* to any incoming surprises (a teacup!). Mechanistically, paying attention to a particular sensory event is proposed to increase the synaptic gain of the cells that are encoding the prediction error (Feldman & Friston, 2010; Smout *et al.*, 2019). Thus, attention is said to turn up the "volume" (Clarke, 2013, p. 22) of the input.

To risk over-stretching the function of attention slightly: the more attention that an event receives, the more real it is. If a change in belief occurs, it is because new information is believed to be true and can be trusted (i.e., has high precision). And since attention is expected precision, then attention modulates reality-correspondence, 'realness', or "felt confidence" in input (Carhart-Harris & Friston, 2019). This reality-shaping effect of attention may be one reason that it plays such a key role in most meditation traditions. Preempting later sections, it is interesting to note that in certain meditations, attention must eventually be released in favor of a form of bare or non-preferential attention, and in yet other meditation practices of the non-dual category, attention is released altogether (Dunne, 2011).

2.4 The inferred hierarchical self

Predictive processing accounts of the self are in the early stages (Milliere & Metzinger, 2020), and there is still not widespread agreement among scientists on a definition of the self. Nevertheless, assuming a predictive brain, we can draw some tentative conclusions. First, like all other aspects of cognition and experience the self must also be a construction built out of hierarchical models driven by past experience. Indeed, according to Friston (2018) and others (e.g., Deane, 2020) possessing a self-model is a natural consequence of active inference and prospection: One cannot predict future actions without representing oneself in those actions. For example, picking up a glass of water requires that we have a model of our body as an intentional agent who *can* pick up a glass of water given certain behaviors. And indeed, we must have a model for that fact that we are an agent that needs such a thing as water. This self-modeling further endows the organism with the ability to consider itself in different future scenarios (i.e., entertaining counterfactuals: I'm thirsty, but I could drink water, or tea). The second implication, which is perhaps more controversial, is that the self is itself hierarchical in nature. We will briefly provide evidence for these ideas below.

It is clear that one's usual sense of self can change, and in seemingly myriad ways. These changes may be usefully put on a continuum, from relatively minor changes (e.g., the retrospective sense that I was acting "not like myself"), to more verifiable concrete changes (e.g., the rubber hand illusion, Botvinick & Cohen, 1998), to changes that are more holistic (e.g., perceiving someone else's body as your own, Petkova & Ehrsson, 2008). Or, on the extreme end, it is also possible to completely disrupt normal self-related processing, such as during a psychotic episode (Sterzer *et al.*, 2018) or high doses of psychedelic drugs (Millière *et al.*, 2018; Timmermann *et al.*, 2018). Such changes to self-representation are usefully accounted for in predictive processing by aberrant priors and precision-weighting (Adams *et al.*, 2013; Corlett *et al.*, 2016; Sterzer *et al.*, 2018), although the mechanisms may vary depending on the specific case. Nevertheless, since subjective experience - including therefore any self-models (Blanke & Metzinger, 2009) - is inferred through Bayes-optimal inference under the predictive processing scheme, the existence of aberrant self-perceptions are *not* surprising (e.g., in the context of the rubber-hand or full-body illusions, highly precise sensory input contradicts proprioceptive input leading to a misperception of ownership). Taken together, the fact that the self is constructed is not controversial because it is prone to change and can even disappear under predictable conditions (e.g., virtual reality, psychopathology, or psychoactive substances).

Is the self also hierarchical? Gallagher (2000) made the now well-known distinction between a *narrative* and an *experiencing* self. The narrative self is embedded in our thoughts and includes our stories about the past, the future, and all our self-referential knowledge and beliefs. On the other hand, the experiencing self refers to our awareness of bodily sensations and events occurring in the present moment. The narrative self is perhaps neurally instantiated by the default-mode-network (DMN; Raichle, 2015), which is associated with key features of high-level cognition, especially mental time-travel (Østby *et al.*, 2012) or more basic forms of counterfactual thinking (Van Hoeck *et al.*, 2013). Indeed, Carhart-Harris & Friston (2019) propose that "...the human DMN can be considered to sit at the top end - or center - of a uniquely deep hierarchical system...". The experiencing self is likely instantiated by task-positive and interoceptive networks (that are anti-correlated with the DMN), including executive and control areas in the prefrontal cortex and anterior cingulate cortex (Fox *et al.*, 2016) as well as the anterior insula (Seth, 2013) and other subcortical regions associated with homeostatic functions (Damasio, 2012).

Within the predictive processing account, abstract thought and therefore the narrative self is placed *higher* in the predictive hierarchy (*temporally thick*, Carhart-Harris & Friston, 2010). On the other hand, sensory and interoceptive input and therefore the experiencing self would be lower in the hierarchy (*temporally thin*, Friston, 2008). There may also be a minimal form of self even lower in the hierarchy, such as the first-person perspective itself, but this is still debated (Blanke & Metzinger, 2009; Sebastian, 2020). Moreover, in recent years experiments and a growing database of personal accounts are leading many researchers to accept the existence of *self-less* states (see Milliere & Metzinger, 2020 for a special issue). It is also worth mentioning how a minimal or basal form of self might arise (though this is an area of considerable debate). As alluded to earlier, self-modeling may be intimately tied to action, because one cannot model one's own action pathways without modeling oneself as a hidden cause. Simply put, the brain needs to model a 'self' in order to predict future states that the 'self' might inhabit. Along this line of thought, Friston (2018) suggested that self-awareness arises whenever a system generates action predictions, and thus aims to minimize the *expected* free energy resulting from those actions.

2.5 Fact free learning and insight

In the above we discussed the different roles that attention (i.e., precision weighting) and active inference (i.e., mental/physical actions) play in the revision of beliefs (priors). However, there is another way to refine generative models that doesn't involve active inference or novel sensory input, known as *fact free learning* (Friston *et al.*, 2017). Aha! moments or insights instantiate fact free learning because they involve the discovery of a solution, idea, or perspective without new information. For example, we might unexpectedly discover a solution while taking a shower or while engaged in another task (Metcalfe & Wiebe, 1987; Ovington *et al.*, 2018). Moreover, experiments show that such insights are usually correct (indicative of refinement, Salvi *et al.*, 2016) and can change subsequent beliefs (indicative of model revision, Laukkonen *et al.*, 2020).

Take the simple example of an anagram. An anagram is a scrambled word, such as "nirtostcpeion". If it is not immediately clear what the hidden word is, then at a certain point it may suddenly become clear, without any new input or facts. We can also speed up the process with a clue: "*Looking inward*"[7]. Similar to anagrams, there are many instances wherein a novel perspective or idea is gained without necessarily being exposed to anything new. Central to fact free learning is that insights arise because the brain continues to refine and compress models through *Bayesian model reduction* (Friston *et al.*, 2016). Bayesian model reduction entails finding simpler and more parsimonious models using only posterior beliefs (i.e., not using sensory outcomes, Friston & Penny, 2011). This process of refinement is comparable to the "...physiological processes in sleep, where redundant (synaptic) model parameters are eliminated to minimize model complexity" (Friston *et al.*, 2017, p.2638). As models undergo refinement and selection - thus making them more parsimonious explanations of sensory input - they can also engender new discoveries, such as the discovery of a new perspective (generative model) that permits a novel insight (or inference, Friston *et al.*, 2017).

Friston *et al.* (2017) suggest that fact free learning may not only occur during sleep but also result from reflection (or *introspection*), both explicit and implicit: "...Having acquired data, the "good scientist" reflects on what she knows (and perhaps sleeps on it), implicitly testing plausible hypotheses of a progressively simpler (less complex and less ambiguous) nature that could provide an accurate account of the data at hand" (p. 2666). The connection between fact free learning, insight, and meditation is therefore quite obvious. Meditation is in many ways the embodiment of fact free learning, by virtue of its emphasis on stillness (both in body and mind) or *in-active* inference. Moreover, meditation can induce extraordinary, novel mental experiences ("input"), that cannot easily be accounted for by existing models, increasing their uncertainty and necessitating revision. Thus, although we argue that meditation practice in essence reduces counterfactual abstract processing, it is simultaneously an opportune moment for model revision and selection as the brain - despite the reduced activity of body and mind - continues its prerogative of hierarchical prediction-error minimization via internal hypothesis testing: "...much like a sculpture is revealed by the artful removal of stone" (Friston *et al.*, 2017, p. 2669). The prospect that meditation engenders insight is also at the very foundation of (for example) classical Theravada Buddhism and vipassanā (insight) meditation practice, which aim to permit specific insights into the workings of one's mind, discussed further below.

3. Meditation

It is now worthwhile to return briefly to our central thesis in light of the previous sections. Our core proposal is that meditation gradually reduces the temporal depth of processing[8] in the predictive hierarchy by bringing the practitioner more and more into the here and now. This process gradually prunes the counterfactual tree, reducing the brain's tendency to abstract temporally thick predictive models. Ultimately, since self-related processes imply temporal depth of processing (Friston, 2018), being fully immersed in the here and now may also occasion a radical shift in one's ordinary sense of self-consciousness. Moreover, meditation may also foster fact free learning (insights), where one's models are refined without active inference.

To prepare for a more nuanced overview of our model, in this section we briefly describe three categories of meditation most studied in contemplative science, that also represent three main classes of meditation in Buddhism (for much more detailed reviews of these practices see, Dahl *et al.*, 2015; Dunne, 2011; Lutz *et al.*, 2007, 2008, 2015). These three categories (FA, OM, and ND) are umbrella terms that do not capture the full diversity found in Buddhist theories and practices. Moreover, similar practices are found outside of Buddhism, for example in Advaita Vedanta and Sufism (Dahl *et al.*, 2015). The practices are also not always clearly distinct and multiple techniques may be used throughout one's training (Lutz *et al.*, 2008). In the Buddhist tradition, ND meditation (Lutz *et al.*, 2006) is particularly emphasized within Mahayana and Vajrayana Buddhism (so-called non-dual traditions). So far, most research on ND meditation has focused on Mahamudra and Dzogchen from the Vajrayana tradition (Antonova *et al.*, 2015; Josipovic, 2010).

As we describe each meditation technique, we also highlight key ways in which they may affect predictive processing, though these notes will be made more formally in the next section. Our central hypothesis here is that each meditation style gradually draws predictive processing closer and closer to the here and now (i.e., less abstract hierarchically deep processing).

3.1 Focused attention

Focused attention (FA) is often practiced when one begins meditation. It involves the explicit focus on a particular aspect of one's present moment sensorium to the exclusion of everything else. The target of one's attention is often the breath, but ultimately any object in present moment experience, like a candle or one's feet while walking, can serve the same purpose. The primary aim of this practice is to stabilize one's attention in the present moment. When thoughts or mind-wandering episodes arise, attention is guided back to the sense object. Thus, FA also involves monitoring or meta-awareness of the quality of attention on the object. With practice and the development of meta-awareness it is said to become easier and eventually effortless to sustain attention on one point of focus in the present moment. Crucially, FA may help to develop the first steps of dereification that are foundational for more "advanced" practices: the ability to discover that all of one's experience is a process rather than a true reflection of reality (Lutz *et al.*, 2015). The development of meta-awareness and dereification permit an easier transition to more advanced practices in which these aspects are further developed (Lutz *et al.*, 2015), as discussed further below. Yet, experienced practitioners may continue to practice FA at the beginning of a meditation period to initially stabilize attention, and indeed may continue to practice FA for other reasons, such as the achievement of deep states of tranquility (Wallace, 1999).

From a predictive processing perspective, we propose that FA meditation *increases the precision-weighting of one source of present moment sensory experience*, and thereby reduces the frequency of abstract thought and the narrative self, i.e., mental processes that rely on deep temporal models. By confining experience as much as possible to one prediction (e.g., breath sensations), FA automatically encourages less habitual 'grasping' of other predictions (such as thoughts), and reduces their appearance (as their relative precision-weighting is diminished). Novice practitioners may have trouble sustaining their attention at one point of focus, reducing the precision assigned to the corresponding sensory signals, providing space for mental distractions (e.g., mind wandering). Advanced practitioners may reach a kind of 'focused homeostasis' once distracting counterfactual hypotheses become sufficiently infrequent. Another natural consequence of restricting awareness to one "object" of experience is that with more advanced practice, one is no longer engaged primarily in the narrative self, and instead is in a less abstracted, present moment mode of experiencing.

As noted earlier, expected precision prescribes reality-correspondence, 'realness', or "felt confidence", so the up-weighting of precision for the input of the FA object (e.g., the breath) should also lead to a relative down-weighting of predictions higher in the hierarchy (e.g., thoughts), and this in turn may reduce the subjective realness of distracting thoughts and feelings and provide a first step towards dereification (Lutz *et al.*, 2015).

3.2 Open monitoring

Open monitoring (OM) may follow after one's mind is sufficiently anchored in the present moment through FA. The practitioner may then begin to gradually open the scope of attention to the broader field of experience: A kind of 'open monitoring'. Particularly in Theravada Buddhist schools of meditation, FA practice is often used to prepare the meditator to practice OM, which is believed to permit deeper insights into the nature of the mind (Lutz *et al.*, 2007), namely: impermanence (aniccā), non-self (anattā), and suffering (dukkha). During OM, one does not sustain attention to an explicit object of experience. Instead, in an open and receptive way one allows whatever arises in experience to come and go: sensations, thoughts, or feelings, or other states of mind, without judgement or evaluation. The focus of this practice is in the cultivation of meta-awareness and in dereification from the contents of experience. In other words, everything that appears in experience is treated equally from the perspective of a nonjudgmental observer. OM may initially require some effort to maintain awareness in the here and now, and explicit attention may be briefly given to the different events that appear in experience (e.g., through a practice of labeling the contents of experience). Advanced practitioners are said to be able to effortlessly observe experience as a whole, without being 'caught' by thoughts, emotions, or anything else that arises in one's sensorium. This way, mental events "lose their representational integrity and are experienced simply as mental events, situated and embodied within a field of sensory, proprioceptive, affective, and somatic feeling tones" (Lutz *et al.*, 2015). Thus, in OM, awareness of the background of experience further comes to the foreground, as one develops the ability to rest in a stable sense of pure experiencing.

Although oscillation between FA and OM may often occur during practice, unlike the directed focus of FA, OM treats all arising signals non-preferentially (e.g., a thought, an emotion, or a sensation). Thus, from a predictive processing perspective, any content of experience is assigned equal precision, and consequently *low precision* in relative terms. Crucially, the goal of OM is *not* to stop experiences from arising. Instead, one reduces 'grasping' by quickly letting arising experiences (predictions) go without confirmation, by maintaining a restful but alert state of non-judgmental observing. Thus, OM continues to reduce the precision and temporal span of predictions arising in experience. As restful non-judgmental observing increases, the system may begin to experience a kind of 'pure' sensing without evaluation. This 'pure experiencing' is conceivably temporally *prior to* evaluations of the sensory experience. For example, sensations in the knees or back during sitting meditation may occur prior to the evaluation of the experience as "painful". This is what is believed to allow practitioners to sit for extended (sometimes many hours) at a time without moving. Thus, *non-judgmental experiencing could be said to be the natural state of the system at a lower level of the hierarchy*. We therefore propose that as the frequency and temporal span of predictions such as thoughts, emotions, and sensations, decreases, then a hierarchically lower layer of the predictive hierarchy (non-judgmental experiencing, or experiencing prior to evaluation of experiencing) dominates. This state is different from FA since no experience is given preferential precision-weighting, and thus 'attention' becomes 'bare' rather than 'object-oriented'.

Under this scheme, the novice OM practitioner experiences more frequent and temporally extended predictions with higher average precision than the experienced OM meditator. The more precision the prediction errors are assigned, the more likely the corresponding content is to 'eclipse' one's mindful (non-judgmental) observation. As expertise increases, the temporal span, precision, and frequency of predictions decreases, making more 'room' for background awareness. With even further practice, experiencing may lose its evaluative quality entirely. The expert OM practitioner therefore should eventually come to rest in a non-judgmental experiencing that we propose is earlier in the predictive hierarchy.

It is also plausible that the practice of non-judgmentally observing and releasing arising predictions could also foreseeably permit *epistemic* changes to the system, in line with classical Buddhism (Bodhi, 2011) and fact free learning (Friston *et al.*, 2017). If all generated predictions (thoughts, feelings, sensations) are continually seen as appearing and disappearing, it would be logical to conclude - have the insight - that they are *impermanent* (aniccā)[9]. Moreover, if one sees that all predictions are quickly interpreted by the system as pleasant or unpleasant leading to craving or aversion respectively (i.e., later in the hierarchy), then one would see the *suffering* (duhkha) inherent in much of experience. Finally, if arising predictions are not under control (i.e., appearing spontaneously), then it is also perhaps recognizable that they - including all embodied sensations and narrative self-centred thinking that are usually ascribed self-hood - are not self-induced, i.e., *do not* have any consistent unchanging self-like character (anattā). In other words, OM by making earlier layers of the predictive hierarchy perceptible may reveal that the embodied and narrative self are just *processes* rather than concrete entities. Buddhist insights may therefore be seen as new priors engendered by OM practice possibly as a result of Bayesian Model Reduction or fact free learning.

3.3 Non-dual

Non-dual (ND) meditation is of growing interest to scientists (see for example, Dunne, 2011; Josipovic, 2010; & Metzinger, 2020)[10]. The key component of this practice is that one aims to discover an awareness that is unchanging regardless of what happens in experience. Metaphorically the "ground of all experience". Some historians propose that this style of meditation was developed later in time than FA and OM meditation, based on emphasizing the idea that there is an awareness that is "beyond" the subject observing experience that is implicated in FA and OM (J. Dunne, 2011; Gyatso, 2010). From the perspective of the 'nondual' discovery, the duality between subject and object is itself a conceptual model constructed from past experience. Clearly FA and OM still have embedded within the practice the duality between an (unconditional) observer and objects that are observed. Thus, as a final 'release' of any abstraction away from the here and now, in ND meditation the idea that there is a distinction between self and objects of experience also falls away. This results in a state of awareness in which there is no background or foreground of experiencing, that is hence devoid of concepts (self, objects), intentionality or the experience of time and space, i.e., a state in which even the most basic constructs of cognition allegedly no longer persist.

It is against this awareness that all cognition is said to arise. It is somewhat paradoxical then to talk about a 'non-dual practice', since the term 'practice' itself implies a duality (someone who is practicing something). Thus, one way to understand the nature of non-dual practice is as follows: *creating the conditions that reduce ordinary cognition that normally 'hides' non-dual awareness*. Such a practice is exemplified in "open presence" and Dzogchen styles of practice within Tibetan Buddhism (Dahl *et al.*, 2015a) and Shikantaza or "just sitting" within the Zen Buddhist tradition (Leighton, 2004). There are also other even older practices with Hindu origins such as self-enquiry in Advaita Vedanta (Dahl *et al.*, 2015) that utilizes questions such as "who am I?" that point attention towards the 'subject' of experience so that its absence may be discovered (Nisargadatta Maharaj, translated talks by Frydman, 1973[11]). For a collection of case-studies describing non-dual experiences see Metzinger (2020), and for a detailed review see Josipovic (2019).

Non-dual meditation, and particularly the qualities of the non-dual experience, is perhaps the most challenging to characterize within the predictive processing framework. However, since all mental experience is constructed through a process of abstraction away from the here and now, then if one were truly to be in the present moment - i.e., not constructing models with temporal thickness - then something akin to a non-dual experience would logically arise. That is, any mental activity that relies on active inference should disappear, including activity related to self-awareness (Friston, 2018; Limanowski & Friston, 2020; Metzinger, 2020). To draw this conclusion, we must assume that some minimal form of experience is still possible without contents or sense of self, though it *may*[12] raise certain philosophical conundrums. As noted by Limanowski & Friston (2020, p. 2), "How could one have a conscious experience - and able to report on it afterwards - in the absence of any awareness of oneself (as having the experience)?".

In search for a naturalistic explanation of ND experiences, Metzinger (2020) developed the concept of minimal phenomenal experience and proposed that non-dual experiences are a Bayesian representation of intrinsic arousal. Indeed, maintaining an optimal level of arousal or alertness is central to many meditation practices. This proposal fits with a large body of work showing that arousal levels causally determine one's level of consciousness and critically enable cortical activity and therefore cognition (Laureys *et al.*, 2009). According to Metzinger (2020), an inner representation of arousal would be expected to possess the characteristics of non-dual awareness described by practitioners, including: "...a complete absence of time-representation and any form of sensorimotor or high-level cognitive content. Further, there would be an absence of low-level embodiment in the sense of spatiotemporal self-location, interoception, and affective background, as well as of higher levels of selfhood like attentional control and cognitive agency." (p. 36). Although there is an absence of representations of self, space, and time, there would nevertheless remain an experience of wakefulness and the *potential* for cognition. A different proposal from Josipovic (2014; Josipovic *et al.*, 2011), although not grounded in the notion of predictive processing, is that non-dual awareness in particular affects the fragmentation of the field of experience into habitual dualities, such as self vs. other, inside vs. outside, good vs. bad, and that this may be brought about by reducing the normally antagonistic relationship between brain networks involved in self-referential processing and external task-related processing (Josipovic, 2014; Josipovic *et al.*, 2011). Future studies are necessary to dissociate between these and other theories.

It is also possible to see how the ND state can potentially go beyond insight or fact free learning, as was the implied goals of OM practice. Having a *conscious* insight moment implies temporal depth, whereby higher levels make predictions about the input of lower levels, and thus refine themselves until a new point of view is uncovered (Friston *et al.*, 2017). Hence theoretically, the ND state ought to be "empty" even of the very possibility to attain conscious insights that characterize OM meditation, assuming that the system is no longer constructing temporally deep models. This appears consistent with perhaps the most popular Mahāyāna (ND) Buddhist scripture, known as the Heart Sutra, which for example states - seemingly transcending the insights of OM practice - that there is "...no truth of suffering, of the cause of suffering, of the cessation of suffering, or of the path. There is no wisdom and there is no attainment whatsoever... And, thus, he passes far beyond confused imagination. And reaches Ultimate Nirvana." (Lok To *et al.*, 2000). The 14th Dalai Lama also noted that the Mahāyāna tradition emphasizes emptiness (¶ūnyatā) of all phenomena (including Buddhist teachings and laws, or *Dharmas*, Gyatso, 2010) whereas classical Theravada Buddhism emphasizes the cessation of suffering, or insight. While we maintain that during non-dual awareness conscious insights seem logically impossible, discovering (perhaps in retrospect) that *everything* is empty can also be considered an insight, as it allegedly qualitatively alters one's subsequent experience of reality. This may suggest that model reduction can also occur during states of minimal temporal depth (cf. in sleep) or happens relatively quickly after coming out of the non-dual state. Moreover, despite 'experiential emptiness' some forms of fact free learning may continue (e.g., selecting between model x and equally probable model y because model *x* is likely to lead to the least surprising outcomes, Friston *et al.*, 2017).

It is important here to note that, although we have placed FA, OM, and ND practice on a continuum of reducing counterfactual or deep temporal processing, we are not claiming that any particular practice or tradition is superior. The interconnectedness and progression of practice highlights that they are in many ways inseparable, and may have different effects that might be perceived as valuable or not depending on the tradition.

4. A Unifying Framework: The Many-to-One Model

Having now laid most of the groundwork for our model, in this section we provide two illustrations and with them aim to capture the key components of the theory. It is perhaps worthwhile restating our aims: The goal of the many-to-one model is to provide a mechanistic predictive processing account of meditation, and in turn reveal how meditation affects the plasticity of predictive processing. In Figure 2 below, we illustrate the effects of FA, OM, and ND meditation specifically as they relate to the depth of processing in the predictive hierarchy. Then, in Figure 3, we illustrate with more nuance how the different meditations effect the time-course of prediction and precision at different levels of the hierarchy.

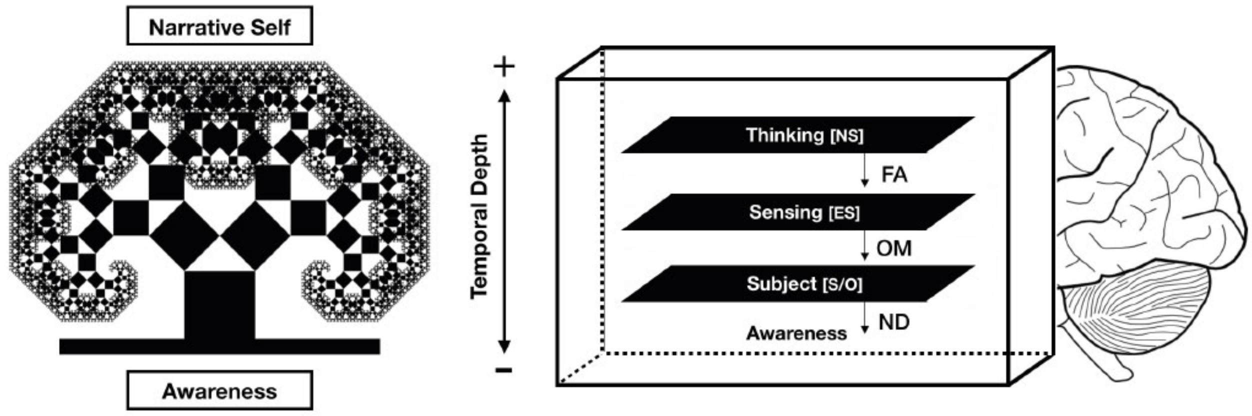

Figure 2. In this schematic we illustrate two aspects of the many-to-one model. The first and most foundational proposal is that meditation gradually *flattens the predictive hierarchy* or 'prunes the counterfactual tree', by bringing the meditator into the here and now, illustrated in the left figure. Thus, meditative depth is defined by the extent that the organism is *not* constructing temporally thick predictions. In the right figure, we dissect the predictive hierarchy into three broad layers. We propose that thinking (and therefore the narrative self [NS]) sits at the top of the predictive hierarchy (Carhart-Harris & Friston, 2010; 2019). Sensing and perceiving and therefore the embodied experiencing self [ES] sits below it (Gallagher, 2000; Seth, 2013). Finally, a basal form of self-hood characterized by the subject-object [S/O] duality sits at the earliest level. FA brings the practitioner out of the narrative self and into a more experiencing and embodied mode of being. Then, through dereification from present moment experience (including bodily sensations) OM brings the practitioner more into a state where contents of experience are treated equally, and one is able to experience non-judgmentally (sensing without appraisal), but even in very advanced states, a subject-object duality remains. During OM, certain epistemic discoveries or insights about the nature and behavior of generative models may occur. Finally, through ND practices the subject-object distinction may fall away and the background or "groundless ground" of all experience - awareness itself - can be uncovered. Another way to characterize this process is as follows: FA employs *regular* (conditional) attention to an object of sensing, OM employs *bare* (unconditional) attention, and ND practice employs *reflexive* awareness that permits the non-dual witnessing of the subject-object dichotomy and finally pure or non-dual awareness.

The above figure provides a broad illustration of how each meditation technique gradually decreases abstraction in the predictive hierarchy. Although we have delineated three layers of the hierarchy to correspond to the three meditation techniques, the hierarchy is of course far more multilayered. For instance, within sensations there is also a hierarchical constructive process, whereby two-dimensional impressions are built into more complex shapes through learned statistical regularities grounded in past experience (Friston, 2005; Serre, 2014). Thus, intensive and prolonged FA practice may also be able to break down sensations into its earlier stages of construction in the hierarchy. Thinking is also likely hierarchical, ranging from simple conceptualization of an object (e.g., noting the observation of a cup), to task-unrelated and disembodied mind-wandering.

We also intentionally did not specify the nature of the subject-object distinction because what precisely constitutes the 'subject' of experience, whether it be a unified proprioceptive model (Friston, 2005; Serre, 2014), or something more basal like witness consciousness (Albahari, 2009)[13], is still debated. Nevertheless, drawing on Friston (2018), we suggest that the experience of being a subject as separate from objects (that is *self*-consciousness but not consciousness per se, see Deane, 2020; Metzinger, 2020) occurs due to predictive models aiming to reduce expected uncertainty. Thus, by being truly present, it may be possible that there occurs a release of any expectations of future states, and thus a 'non-activation' of the most basal self-model and duality itself.

Strikingly consistent with the continuum of decreasing abstraction in our framework, in a recent meta-bioinformatics study of 17,000 experiments and approximately 1/4 of the fMRI literature, Taylor *et al*. (2015) used connectivity models and a data-driven approach to reveal "...an objective hierarchical landscape of cognition in the brain, *with awareness at its structural core*, and all results defined solely by a computational analysis, largely devoid of human bias" (p. 11, emphasis ours). Moreover, ~500 subjects intuitively ranked the behavioral tasks used in the analysis on a spectrum from concrete to abstract, and this ranking - somewhat astonishingly - mirrored the objective physiologically-based ranking. Thus, indicating that the brains functional hierarchy can be considered a process of abstraction further away from the core (awareness) followed by direct sensory input, and then further abstraction in the hierarchy from there (e.g., conceptual thought). An outstanding question following Figure 2 is *how* precisely each meditation technique reduces abstract processing. To this end, in Figure 3 below illustrates how each meditation type changes the frequency and precision of predictions over time.

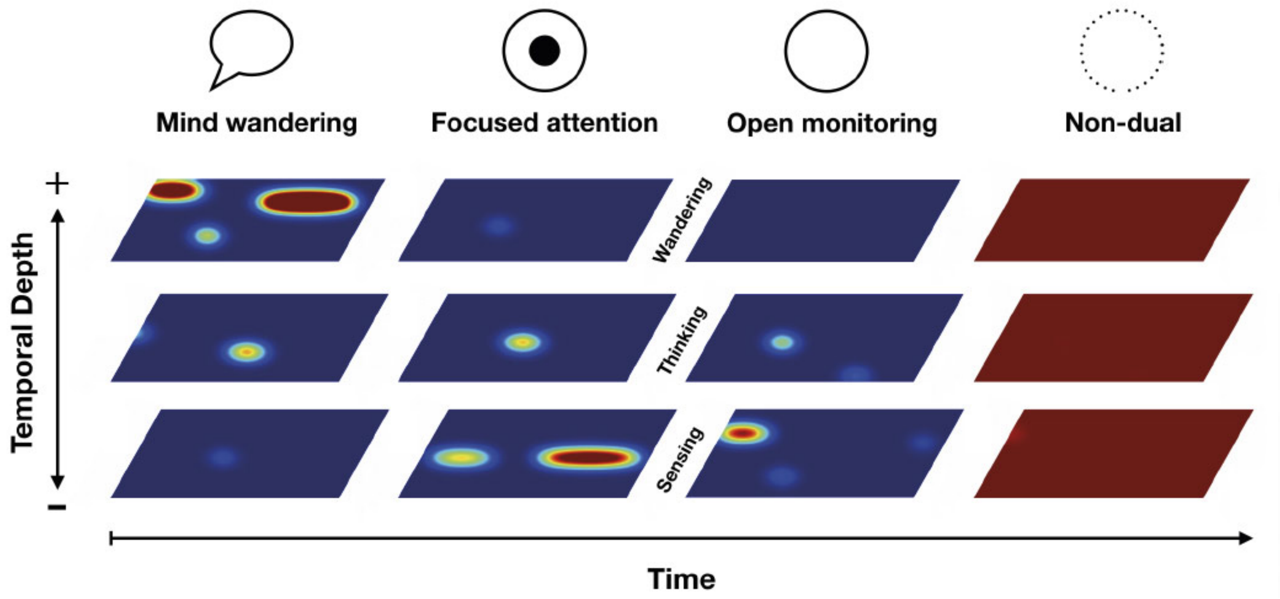

Figure 3. Here we illustrate the precision and frequency of predictions at different levels of the predictive hierarchy during mind wandering, FA, OM, and ND. Blue rectangles represent layers of the predictive hierarchy, with deeper and later layers represented at the top (e.g., mind wandering and the narrative self), task-relevant thinking in the middle, and the bottom rectangles represent earlier layers (e.g., present moment sensory experience). Ovals represent the predictions active in one's experience. The redder the oval the higher the precision-weighting of the prediction. The location of the oval in a specific rectangle represents a different prediction of the same layer of the hierarchy. For example, during FA meditation, one engages attention (increases precision) of a *specific* prediction at earlier layers of the predictive hierarchy (e.g., the breath). With practice, one can sustain attention on the same prediction for a longer period of time while decreasing the frequency and relative precision of predictions higher in the hierarchy. When one practices OM, different predictions will still arise in experience but are assigned lower precision, as illustrated by smaller and lighter ovals. With ongoing practice of OM, predictions arise less frequently and become less 'sticky', thus also disappearing faster. Increasingly experiencing without appraisal (an earlier layer of the predictive hierarchy) dominates as predictions, or contents of experience, become less relevant and capture attention less. Finally, during ND meditation, the awareness inherent in experience becomes the foreground. In FA and OM, predictions within experience are still the prominent event in experience. However, in the ND state, all contents of experience, as well as the subject of experience, fall away, and only awareness (without background or foreground) remains. This is represented by the background of the rectangle becoming red instead of blue. Note that for the FA, OM, and ND categories we have exemplified a relatively advanced practitioner. For a more novice meditator one can generally expect longer, more frequent, and more variable predictions at higher layers of the hierarchy[14].

To our knowledge, what we have described is the first integrated predictive processing account of FA, OM, and ND meditation styles. Although each meditation is proposed to uniquely modulate predictive processes, they nevertheless exist on a continuum where each strategy gradually breaks down increasingly ingrained expectations. Yet, one may wonder if true present-momentness is ever possible, given that also in the ND state, vital bodily parameters must remain within bounds. Thus, we propose that the ND state is characterized by a collapse of predictive processes that possess temporal depth and involve minimization of *expected* surprise. If one is no longer making any predictions about the next moment in time, then there is also no reference for time (i.e., past or future within which to define the present) or a continuous sense of self (i.e., no construct of self that was, is, and will be). Under this view, vital homeostatic predictive processes that operate at low levels of the hierarchy and do not elicit subjective experiences of time and self may continue, such as the maintenance of body temperature and blood circulation within necessary bounds. Yet, obviously, if one would stay in the ND state too long (as in the dark room), one would naturally end up dead. Ultimately, humans, like any living creature, have evolved to occupy a specific econiche that allows them to maintain their boundary, and not dissolve into entropy, which requires for example expectations to eat. Expert meditators report that it is possible not to experience hunger or thirst (indeed any bodily experience whatsoever) during meditation, which makes sense from our perspective given that "...hunger does not simply reflect an inference about hypoglycaemia but the belief that if I act in this way, I will avoid (surprising) interoceptive (low blood sugar) cues. This reflects the quintessentially counterfactual nature of allostatic processing in hierarchical models." (Pezzulo *et al.*, 2015, p. 26). Yet, we experience the world not just with our bodies, but because of our bodies, so ultimately, expectations inherited through evolution about physiological allostasis ought to 'kick in' and drive behavior towards survival, except perhaps in extreme cases[15].

4.1 Predictive processing & meditation: A nascent field

> "...it is easy to see that the FEP [Free Energy Principle] framework appears optimally suited for the scientific investigation of contemplative practices. In fact, it ties together in a coherent theoretical scaffold the core meditative notions of attention (top-down deployment of precision weighting), the conditioning power of habitual self-related patterns of thought and behavior (priors), and the embodied nature of cognition and emotion (interoceptive inference)." (Lutz *et al.*, 2019, p. 167)

Several theoretical proposals have been put forward in recent years about how meditation may affect predictive processing, although none of these distinguished between effects of different styles of meditation (although the existence of possible differences were acknowledged by both Lutz *et al.*, 2019 & Pagnoni, 2019). In a published conversation on predictive processing and meditation between Pagnoni (a neuroscientist) and Guareschi (an Abbot of a Zen monastery, Pagnoni & Guareschi, 2017), the role of attention and bodily posture was emphasized as important ingredients to make generative models more susceptible for revision in light of new inputs (Pagnoni & Hasenkamp, 2017). More recently, Lutz *et al*. (2019) framed FA meditation in predictive processing terms as corresponding to "the selection of a policy that includes the mental action of setting a high precision for the sensory prediction errors associated to the chosen attentional target and the prescribed bodily posture". They furthermore describe the shift from a state of focus to mind wandering as involving two processes: a change in prediction from sensory input (e.g., breath) to mental events (e.g., thought), and a corresponding shift in expected precision higher in the hierarchy (e.g., from sensing to thinking). This characterization is largely consistent with our account of FA meditation, where the goal is to bring attention away from thoughts (predictions high in the hierarchy) via increasing expected-precision of a sensory object (lower in the hierarchy).

Lutz *et al*. (2019) further proposed that FA meditation is characterized by inaction at multiple levels: the level of behaviour (sitting still), vision (e.g., keeping one's eyes centrally directed), and thought (by maintaining attention on a specific object). This non-action radically restricts active inference, and thus reduces the influence of prior beliefs and upweights the influence of sensory evidence. Indeed, past theorizing emphasizes that the strict bodily posture adopted in meditation is not arbitrary (Pagnoni & Guareschi, 2017; Pagnoni, 2019; Lutz *et al*. 2019). Lutz *et al*. (2019) suggested that the posture aids focus by alerting the meditator to mind-wandering whenever one "slouches", thus eliciting a prediction error that brings the meditator back to the sensory object, functioning as a kind of bio-feedback device (Pagnoni, 2019). Pagnoni (2019) also recently connected another specific meditation technique to predictive processing known as Shinkantaza, a form of Japanese (ND) Zen meditation. Interestingly, and at first glance in contrast to our model, Pagnoni suggests that this meditation practice *increases* the counterfactual richness of processing. Noting that this is "paradoxical" given the meditators focus on the here and now, the idea is that meditation weakens ingrained prediction loops and this in turn permits one to entertain a broader set of counterfactuals (particularly outside of formal meditation). Thus, while we propose that meditation itself "prunes the counterfactual tree", this pruning may be precisely what allows the system to *then* embody a more flexible and variable - or more rich - set of counterfactuals post-meditation by down-weighting the precision of ingrained habits of mentation. Put simply, the *state* of meditation decreases counterfactual processing (as we propose), but the enduring result or *trait* of meditation may permit a more flexible and rich counterfactual processing in daily life.

To date, no distinctions were made regarding the way that different styles of meditation may change predictive processing. Moreover, our model takes an important step by proposing a single mechanism that can account for the effects of FA, OM, and ND: They progressively reduce abstract processing in the brain. We also suggest that when viewed as a continuum of 'hereness and nowness', the purpose of these practices go beyond the regulation of cognition, attention, and emotion (as typically emphasized in the literature, e.g., Slagter *et al*., 2011) and instead emphasize the reduction of habitually generating predictions based on past experience. Like previous work, we also acknowledge the crucial role played by the embodied, holistic *inactive inference* of meditation that we think serves to prevent habitual predictions from arising in experience. Our model also goes further to propose how the three main meditation techniques may gradually deconstruct self-related predictions, unraveling increasingly basal forms of self-hood, until that which is even prior to self-modeling can be experienced. And finally, we also provide a framework for understanding how certain key insights may arise through fact free learning, which may cascade a radical revision of one's generative model and key priors.

5. Previous research under a new light

As yet there are only a handful of studies that have specifically tested how meditation affects self-specific processing, engrained habits (i.e., stubborn predictive processes), or that explicitly manipulated prediction formation, which we review in the following section. Nevertheless, existing work seems to align well with our predictive processing account of meditation, and the continuum of effects expected due to FA, OM, and ND practice. The review is divided into experimental and (neuro)phenomenological research. Given the nascent field, our model is also forward looking and we hope that it will inspire many new directions for empirical work at the intersection of meditation and prediction.

5.1 Experimental Research

Much of human waking consciousness is spent engaged in a thinking and narrative mode of being (Killingsworth & Gilbert, 2010), and we have suggested that FA meditation primarily aims to bring about an initial shift from thinking to sensing, laying the groundwork for subsequent practices. FA achieves this 'presentness' by reducing engagement with abstract temporally deep predictions (e.g., thinking) by increasing the expected precision of one source of present sensory experience, increasing the weight of actual sensory input over sensory predictions induced by spontaneous thoughts. This is evidenced by the fact that even very brief mindfulness of breathing (8 minutes) can occasion reduced mind-wandering episodes (Mrazek *et al.*, 2012), and four days (20 min/day) can improve mindfulness scores and sustained attention (compared to an active control group, Zeidan *et al.*, 2010). In a neuroimaging study, Farb *et al.* (2007) also proposed that humans possess a narrative-self bias:

> "The theory of narrative generation as a default state of self-reference is increasingly supported by neural evidence: the cortical midline activity, which underlies narrative-generating mind wandering (Mason *et al.*, 2007) is very similar to activity associated with the 'default mode' of resting attention (Gusnard *et al.*, 2001; Raichle *et al.*, 2001). This default mode suggests an endemic reliance upon the networks supporting temporally extended narrative processing..." (p. 314).

Suggestive that meditation may make it easier to voluntarily shift out of this narrative mode of being, the authors found that participants who underwent an 8-week mindfulness course (which involves characteristics of both FA and OM, Kabat-Zinn, 2003) showed a more pronounced shift in neural activity when volitionally engaging an experiencing versus narrative self-focus. For example, those who underwent the meditation training showed a more "marked and pervasive" reduction in medial prefrontal cortex activity - a key hub of the DMN associated with self-processing - during 'experience focus' compared to controls. In terms of our model, the meditators may have been able to more completely disengage temporally thick predictions in favor of a less abstracted present moment experiencing. Like many meditation studies, there are methodological limitations to be kept in mind: the design was not pre-post and there was no *active* control group, and thus it's hard to determine whether the mindfulness program was the causal factor. Nevertheless, these neural findings are broadly consistent with several other behavioral studies showing that meditation reduces mind-wandering (Levinson *et al.*, 2014; MacLean *et al.*, 2010; Mrazek *et al.*, 2012) and other neuroimaging results indicating that mindfulness reduces activity in key nodes of the DMN (Fox *et al.*, 2016). The prospect that FA can enhance present-moment experience of a sensory object, and reduce mental distraction, is also suggested by findings from an EEG study by Lutz *et al.* (2008), which found that practitioners of a three-month meditation retreat exhibited an increase in the temporal consistency with which the brain responded to auditory tones presented in the attended ear, that was accompanied by a reduction in reaction time variability.

While FA aims primarily to increase one's sustained attention of a sensory object in order to derive a more present and tranquil state of mind, OM meditation withdraws selective attention in favor of a broad scale dereification from the contents of experience. Such non-judgmental experiencing we have suggested equates to a reduction in the relative expected precision of all contents of experience, further increasing present-moment awareness. This should also reduce the development of new expectations. Consistent with this idea, Valentine & Sweet (1999) hypothesized that FA enhances attentional capacity for *expected* stimuli, whereas OM may (relatively speaking) enhance detection of *unexpected* stimuli, because one should not be 'caught up' by expectations. The study included novice (24 months or less) and experienced meditators (25 months or more) who predominately practiced either FA or OM, and a non-meditator control group. The participants were tasked with counting a stream of sounds that were first presented at a slow rate (0.25hz, expected condition), and in a final block, at a much faster rate (7hz, unexpected condition). In the expected condition, overall counting performance was lowest for control subjects, followed by novice meditators, and highest for experienced meditators. Moreover, and in line with their hypotheses, only the *unexpected* condition differentiated between FA and OM meditators, wherein the OM group performed better. These results may suggest that the OM meditators were less biased by the previous temporal regularities in the expected condition, in line with the notion that OM induces a state of present-moment awareness in which experience is less influenced by what just happened or may happen in the future. Another possible explanation is that, because the unexpected condition was also *faster*, then OM meditators were better able to 'release' each appearing stimulus in order to count the subsequent sound.

Slagter *et al*. (2007) showed a similar effect using the well-established attentional blink task. After 3 months of OM practice under intensive retreat conditions, participants showed a smaller attentional blink (i.e., the ability to notice a target stimulus (T2) that is rapidly presented after another target stimulus) compared to a control group. This finding was also backed up by EEG measurements that showed a smaller P3b to the first target (T1) stimulus, which is a brain potential that is associated with higher-order stimulus processing. These results make sense within our framework: if each passing stimulus is assigned lower precision, then the first target is less likely to capture attention, permitting better detection of T2. More specifically, these data support our hypothesis that OM meditation brings the practitioner more into a state of non-judgmental direct experiencing (i.e., lower in the temporal hierarchy of processing). More shallow processing means faster 'letting go' (better behavioral performance), which is further reinforced by a smaller P3b in meditators (an index of temporally deep processing).

We have also suggested that meditative depth can essentially be defined by the modulation of increasingly engrained habits or expectations. Thus, we would expect that more advanced meditation practices and greater expertise would permit the modulation of more stubborn predictions (or reactions to prediction-violations). Next, we briefly discuss four paradigms where this has been studied in the context of meditation - neural markers of prediction errors, startle responses, analgesic effects, and binocular rivalry. Each of these paradigms invoke an experience or reaction in the organism that is ordinarily believed to be automatic. However, below we outline some preliminary evidence suggesting that meditation may be able to modulate these responses by - we suggest - preventing the construction of temporally deep predictions grounded in past experience. These findings therefore are also revealing about the plasticity of predictive processing more broadly. In many cases, the evidence is also consistent with the idea that expertise and practices that go beyond FA are required to induce effects on more stubborn predictions.

A promising method for investigating the effect of meditation on prediction is the odd-ball paradigm, where a surprising (usually auditory) stimulus is presented after several repetitions of predictable stimuli. EEG studies show that the deviant stimulus ordinarily evokes an auditory event-related potential known as the mismatch negativity (MMN) thought to be a kind of neural correlate of prediction errors (Garrido *et al*., 2009). Initial investigations of FA meditation found increased MMN in response to surprising auditory stimuli (Srinivasan & Baijal, 2007), indicative of the development of more precise sensory expectations through FA. There is also evidence of trait effects, whereby experienced meditators showed a larger MMN than novices also while not meditating (Biedermann *et al*., 2016). These results are consistent with the idea that FA meditation leads to increased attentional capacities for low-level sensory stimuli. However, other meditation practices, according to our model, also involve a *retraction* of attention and precision-weighting to any particular components of experience, in favor of a more holistic and *bare* attention towards one's experience as a whole as in OM, or releasing of attention all together, as in ND. Interestingly, Fucci *et al*. (2018) recently found that FA meditation lead to a higher MMN than a control condition (as in Biedermann *et al*., 2016), but ND meditation did not. Non-dual meditation showed approximately the same degree of MMN as a control 'reading' or "distracted" condition, and the difference between practitioners in the FA versus ND was only different at the trend level. Thus, ND meditation in this study did *not* abate the MMN as would be expected if the meditator were genuinely not forming expectations across time. Expertise in ND meditation is hard to establish (i.e., it is very difficult to say if participants were genuinely in such a state). It is also possible that low-level neural signatures of oddballs are sufficiently automatic that they cannot be eliminated by changes in mental state (see below for a study where a higher-level prediction error is attenuated by meditation). Yet, it has been shown that the prediction error-related MMN vanishes during deep sleep (Strauss *et al*., 2015). Future research is necessary to replicate this finding by Fucci *et al*. (2018) and will be critical for establishing which predictions are capable of change through meditation and which are truly stubborn.

In a related paradigm, Kirk & Montague (2015) found that Zen meditators (compared to controls) showed *no* reward-related prediction error responses as measured by fMRI. In this experiment, participants were not meditating; thus, the results likely represent trait effects. One explanation is that, by resting in the here and now, the meditators were no longer constructing inferences about the positive or negative valence of an event. The other possibility is that Zen meditation, because it is primarily a ND tradition, makes it possible that the effect is due to a modulation of prediction error signaling more broadly.

Clearly, further research is needed to properly disentangle the relationship between FA, OM, and ND meditation on prediction error signaling. Nevertheless, we see these results as providing preliminary evidence that FA increases expected precision-weighting of sensory experience leading to higher prediction-error signaling (Srinivasan & Baijal, 2007), whereas the more advanced practices such as ND retract precision-weighting of any specific content of experience - emphasizing awareness itself - making stimuli less surprising in general (Fucci *et al*., 2018; Kirk & Montague, 2015). Yet, as noted above, some predictions, like the oddball effect, may be evolutionary engrained and difficult to abolish even by experienced meditators.

Representing another highly automatic process, the startle response is believed to be a phylogenetically primitive defense reflex (Koch, 1999). Testing whether meditation may lead to modulations in the startle response, Levenson *et al*. (2012) found that a highly experienced meditator (40 years of practice) showed a smaller startle response when meditating compared to 12 control subjects. Notably, ND meditation resulted in the smallest startle response (relative to FA), consistent with our framework. In another study investigating *habituation* to the startle response, Antonova *et al*., (2015) reported no evidence of habituation in 12 expert meditators who were instructed to rest in a non-dual state while being presented with startling sounds. Interestingly, participants with moderate meditation experience showed more habituation than control subjects, highlighting that expertise or depth of meditation may not be a linear process, but something more akin to an inverted U-curve. In contrast to Levenson *et al*. (2012), Antonova *et al*. (2015) found no effect of meditation on the initial startle reflex, which they propose might be due to the meditators being less experienced or due to the use of a weaker startle stimulus in their study. These studies provide preliminary evidence that expertise and advanced practices lead to the largest modulations of the startle response, both in terms of the initial reflexes elicited by a "surprising" stimulus (Levenson *et al*., 2012) and in terms of startle habituation, a form of learned inhibition (Antonova *et al*., 2015; see also Hanley & Garland, 2019 for evidence that mindfulness training can reduce Pavlovian conditioning).

The experience of pain is also a highly automatic inference. But, like other subjective experiences, under the predictive processing framework, pain is the outcome of an inferential process. Thus, being fully immersed in the here and now - i.e., not constructing temporally deep models - it would *theoretically* be possible for meditation to modulate the construction of painful experiences. Indeed, there is growing evidence that some forms of meditation can have such analgesic effects. Grant (2014) reviewed experimental work on the effects of meditation on pain reduction and found that OM meditation but *not* FA showed consistent and relatively strong reductions (up to 23%, Grant & Rainville, 2009) in pain intensity ratings (see also Zeidan & Vago, 2016). Such findings are also supported by differences between meditators and non-meditators in neural activity both before and during the painful stimulus (Lutz *et al*., 2013). Reductions in experiences of pain may be driven by different mechanisms, for example the most complete cessation would occur if one were able to halt pain prediction entirely. Such a finding would theoretically be possible in a ND state. However, it is more likely that existing findings represent a more modest deconstruction of predictive processes, where OM meditation leads to less anticipation and/or judgment of the pain as aversive (Lutz *et al*., 2013). Consistent with this idea, Perlman *et al*. (2010) found that OM (but not FA) lead to significantly lower ratings of unpleasantness for painful stimuli, but *not* intensity. This finding also makes sense under our framework where OM works to reduce the temporal depth of processing to a more direct experiencing prior to appraisal/judgment.

Finally, the phenomenon of binocular rivalry highlights how past experience affects the most basic levels of perceptual experience. In this task, two images are presented separately to each eye (e.g., a face and a house), which leads to a fascinating phenomenon wherein the observer perceives an alternating face *or* house image (and sometimes a mix). Under the predictive processing framework (Hohwy *et al*., 2008), the rivalrous perception occurs because the input violates the brains expectations that two different images can occur in the same spatio-temporal location. Thus, past experience prevents the perception of the 'true' input, i.e., a coalesced face-house image. Moreover, perception continues to switch between percepts because the unperceived stimulus continues to trigger prediction errors until it leads to a revision in the posterior hypothesis (and the cycle continues). Intriguingly, Carter *et al*. (2005) presented binocular rivalry stimuli to Tibetan monks with extensive meditation experience. The authors found that one-point meditation (an advanced form of FA) reduced perceptual switch rates (including three monks who experienced a stable stimulus for the whole five-minute period!). From the predictive processing perspective, this makes sense if the meditators, through FA, increase the precision of the prediction errors of the attended stimulus (thus, overpowering prediction errors from the unperceived stimulus). The authors also found something highly unusual: One of the monks reported experiencing a prolonged so-called 'mixed percept'. Under the predictive processing framework this suggests that the stubborn prediction 'two images cannot appear in the same spatio-temporal location' was broken down[16]. Carter *et al*. (2005) concluded that "These results contrast sharply with the reported observations of over 1000 meditation-naive individuals tested previously". Since it is difficult to maintain deep states of meditation while providing responses, several subjects were not comfortable in responding during the experiments, and thus the results were dependent on post-hoc self-reports. An important direction for meditation research is to develop paradigms that do not interrupt the meditation, but can track neural representations and perceptual experience, which we address in the Discussion.

In the above, we discussed several key findings from meditation studies to showcase how these findings may be re-understood based on our many-to-one model, and how meditation may shed novel light on the extent to which predictive models are plastic versus stubborn. In the below, we discuss meditation-related changes in self-reported phenomenal experience in relation to our model.

5.2 (Neuro)Phenomenological Research

Perhaps the most radical evidence for the deconstruction of the predictive processing hierarchy is found in the self-reported phenomenology of expert meditators. Indeed, many generations of practitioners from Buddhist meditation traditions have theorized about subjective experiences that are expected to occur at specific stages of practice (Bodhi, 2011; Wallace, 1999). Many expert meditators also report being able to access such states on demand, and there is now a growing effort to map these subjective experiences under controlled settings and to identify corresponding neural changes (Dor-Ziderman *et al*., 2013, 2016, 2016; Petitmengin *et al*., 2017, 2019). These reports support the notion that more advanced states correspond to the breaking down of increasingly engrained habits of mentation, including perceptions of selfhood, space, and time: Experiences that are supported by unique and consistent neural signatures (Berkovich-Ohana *et al*., 2013). In the following we describe some of the studies conducted on meditative phenomenology as they relate to our model. We are primarily interested in the possibility that meditative (neuro)phenomenology can provide evidence of the deconstruction of highly engrained models, thus offering initial evidence that predictive processes may be more malleable than previously thought.

Below we particularly focus on changes in the sense of self, since it is the explicit aim of some meditation techniques (Dahl *et al*., 2015) and has received the most (neuro)phenomenological research. Changes in the self-sense is also central to our model, which proposes that meditation gradually permits the discovery of increasingly basal forms of selfhood, culminating in the ND state, where the practitioner is "resting" in/as the here and now to the extent that there is no self-awareness or temporal experience whatsoever.

In a seminal neuro-phenomenology study by Dor-Ziderman *et al*. (2013), 12 experienced vipassana meditators were instructed to enter 3 states of "self-awareness" while MEG recordings were made. The three states - similar to our characterization - were: the narrative self, the minimal self (or experiencing self), and the "self-less". Self-less experiences were defined by a lack of agency or ownership. One subject described such an experience as follows, "It was emptiness, as if the self fell out of the picture. There was an experience but it had no address, it was not attached to a center or subject..." (Dor-Ziderman *et al*., 2013, p. 6). Nearly all participants reported success in accessing all three states of self-awareness and in maintaining them for the duration of the instructed period. Consistent with the idea that deeper and more self-less states involve less conceptual processing (placing them lower in the predictive hierarchy), the minimal self and self-less conditions also showed a dramatic reduction in self-reported emotions (negative, positive, and mixed) compared to the narrative self. Furthermore, consistent with extensive fMRI research on self-related processing (Gusnard *et al.*, 2001), attenuation of the narrative self was supported by decreases in gamma oscillations source localized to frontal and particularly medial prefrontal cortices. And finally, some of the highly experienced meditators who reported the most vividly self-less experiences showed additional attenuation of the inferior parietal lobule and left dorsomedial thalamus in the beta band (Dor-Ziderman *et al.*, 2013). As noted by Dor-Ziderman (2013), the inferior parietal lobule has been implicated as a key region associated with the sense of agency and subjective control (Nahab *et al.*, 2011).

In another study with a similar design, Dor-Ziderman *et al.* (2016) focused on the phenomenology of an advanced meditation practitioner who was entering into a state of ND awareness. Consistent with the previous study, the transition from a minimal form of self-experience to a self-less state was associated with changes in beta oscillations localized to the temporo-parietal junction (TPJ, including the inferior parietal lobule, as in the previous study) as well as the medial parietal cortex including the precuneus (a key node for self-representation). The TPJ has been extensively shown to play a key role in self-related processing, including self-awareness, self-location, agency and ownership, egocentrism, and the experiential unity of body and self (Dor-Ziderman *et al.*, 2016). Another study using functional magnetic resonance imaging (fMRI) in 24 Tibetan Buddhist meditation practitioners suggests that ND meditation may lead to alterations in interactions between intrinsic networks involved in self-referential processing, of which the precuneus is a central node, and extrinsic networks involved in external, task-related processing (Josipovic *et al.*, 2011). This finding is consistent with the idea that ND practice particularly influences the habitual organization of cognition along a subject-object dichotomy.

Most recently, Winter *et al.* (2020) reported data from joint EEG-fMRI while an extremely experienced meditator with over 40 years and approximately 50,000 hours of practice entered a ND state. The participant reported afterwards that towards the end of the meditation, he experienced no mental or sensory content whatsoever, including no self, time, or space, but *did* report maintaining a steady 'wakefulness' throughout the whole period. Compared to a resting state baseline, the subject showed sharp decreases in alpha-band power (EEG) and functional connectivity of the DMN (fMRI). This latter finding is in line with the research reviewed above, as Winter *et al.* (2020) also noted: "The interplay between the medial and lateral parietal nodes of the DMN has been found to be associated with meditative experiences of non-dual awareness (Josipovic, 2014), selflessness (Dor-Ziderman *et al.*, 2013), spacelessness and timelessness (Berkovich-Ohana *et al.*, 2013)".

The above studies together suggest that some meditators can volitionally enter states that gradually deconstruct self-representations, including the narrative self and the minimal self (Dor-Ziderman *et al.*, 2013, 2016), and through more advanced practices may be able to collapse the subject-object distinction (Josipovic, 2014; Winter *et al.*, 2020), which are corroborated by relatively consistent neural signatures. According to our model, this gradual deconstruction of the self-hierarchy is a natural consequence of resting in the here and now, because as meditation 'prunes the counterfactual tree' (flattening the predictive hierarchy) it necessarily also prunes one's sense of self, from a narrative form of selfhood all the way to selfless awareness.

Achieving advanced states of meditation is not a process that is always experienced positively, and that challenging and even impairing experiences can arise (Lindahl *et al.*, 2017; Lindahl & Britton, 2019). In some cases alterations to the sense of self are also experienced as distressing or resembling psychopathology (Lindahl & Britton, 2019). Thus, the outcomes of (especially) more intensive meditation may not coincide with the goals of mindfulness practice for many lay practitioners (e.g., reducing stress, being more productive), a possibility we return to in the Discussion. The above review is not intended to be exhaustive, but a focused review of key papers that are revealing about the flexibility of predictive processing during different meditation practices. In the Discussion, we return to issues of methodological rigor and propose promising novel paradigms that may strengthen the above findings and improve our capacity to experimentally investigate deep states of meditation.

5.3 Dissolving or disappearing: Psychedelics and meditation

There seems to be some merit in briefly comparing our predictive processing account of meditation to recently formulated predictive processing theories of psychedelics. The reason for this is four-fold, 1) psychedelics and meditation both show deconstructive effects on predictive processes, 2) they can both radically alter one's sense of self (Millière *et al.*, 2018), 3) they show some neuro-biological similarities (Millière *et al.*, 2018; Timmermann, Spriggs, *et al.*, 2018), and 4) they are both thought to lead to novel insights about the workings of one's mind and can exhibit positive effects on mental health (Carhart-Harris & Friston, 2019). Although there are clear conceptual similarities, there are also important differences between our account and predictive processing models of psychedelics. Highlighting some of these may help guide future research on the intersection of meditation and psychedelics (for recent examples see, Millière *et al.*, 2018; Milliere & Metzinger, 2020; Smigielski *et al.*, 2019). Below we focus on the recent predictive processing model of psychedelics termed relaxed beliefs under psychedelics, or REBUS for short (Carhart-Harris & Friston, 2019). Although competing models exist (Swanson, 2018), the REBUS model shows growing empirical support (e.g., Alamia *et al.*, 2020; Girn *et al.*, 2020; Herzog *et al.*, 2020).

According to Carhart-Harris & Friston (2019), psychedelics induce their characteristic effects on phenomenology by inducing increased entropy via agonism of the serotonin 5-HT$_{2A}$ receptors found predominately at high levels of the cortical hierarchy. This entropy purportedly leads to a breakdown of the DMN and temporally deep priors that ordinarily constrain input from lower layers of the hierarchy. These loosened beliefs in turn permit a kind of unconstrained "anarchic" phenomenology, where predictions that would ordinarily be explained away by deeper models, now arise in conscious experience. Moreover, since the classic psychedelics - e.g., psilocybin and lysergic acid diethylamide (LSD) - are thought to effect the highest levels of abstract processing, then self-related processing (especially that which is instantiated by the DMN, Carhart-Harris *et al.*, 2014) is expected to breakdown. One similarity with our account is that meditation should also engender relaxed high level beliefs by decreasing their expected precision. But perhaps unlike psychedelics, meditation may radically reduce the frequency of high-level predictions (such as mind-wandering) and the very formation of some predictions. That is, we contend that the three meditation styles gradually reduce deep predictions from arising (e.g. thoughts, emotions, senses), ultimately resulting in the non-dual state. This contrasts with states induced by most psychedelics, including drug-induced ego dissolution, which often have a rich sensory and emotional phenomenology (Millière *et al.*, 2018).

Both psychedelics and meditation also result in consistent reports of experiences where one's usual sense of self changes (see Millière *et al.*, 2018 for a review). We have suggested that the reason these changes in self experience occur in meditation is through a gradual reduction in temporally deep processing by resting in the here and now. On the other hand, following the REBUS model, changes in self-processing purportedly occur due to the entropic effects of psychedelics on existing priors (which may also 'flatten' or 'collapse' the hierarchy, Girn *et al.*, 2020; Deane, 2020), and thus ordinary self-modelling breaks down. Thus, we propose that meditation gradually *abates* the emergence of predictions by restricting awareness to the here and now, whereas psychedelics loosens priors and, in this way, leads to the dissolution or "mergence" of self-world boundaries in experience. Or put simply, meditation *reduces* counterfactual inference, whereas psychedelics disrupt it. This difference is evident in the fact that self-less experiences during psychedelic ingestion tend to be described with high phenomenal richness whereas meditative experiences often have very little (or no) phenomenal content. Claims of "unity", or "oneness" with the environment, and statements such as "...merging with my surroundings" are common among psychedelic reports (Millière *et al.*, 2018). On the other hand, meditators more commonly report "emptiness", "space", and "nothing" (Metzinger, 2020; Millière *et al.*, 2018). Indeed, if the experience is truly non-dual, then there should be no experience of self, environment, or their 'mergence'. These reports are not surprising under our account, where meditation abates counterfactual processing, whereas psychedelics relax them. Put simply, we suggest that meditation prunes the counterfactual tree, whereas psychedelics dissolve it, both leading to possibly unique changes and absences in one's sense of self (see Figure 4).

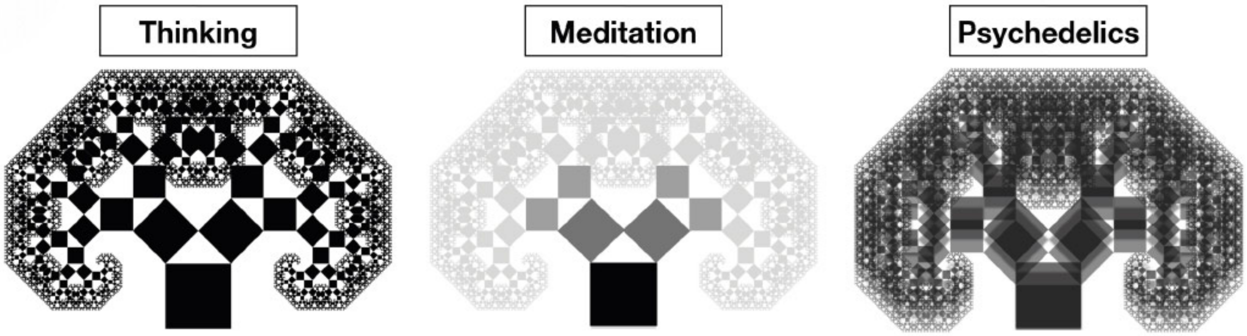

Figure 4. Here we provide an intuitive illustration of how meditation and psychedelics may differentially affect counterfactual processing. On the one hand, the psychedelic state may lead to greater counterfactual richness through its reduction of sensory gating, where relaxed high-level beliefs release low-level predictions (or counterfactuals) that would normally be explained away. Existing priors about one's self and bodily representation may then begin to dissolve because the usual models that maintain such boundaries are less precise (or *relaxed*). On the other hand, in the meditative state, counterfactual processing is gradually reduced, permitting a more progressive reduction in self-related processing, first at the higher levels (e.g., narrative self) and later at the lower levels (e.g., embodied self). During psychedelics, narrative and experiencing aspects of self-hood may begin to dissolve simultaneously and affect each other in innumerable ways, which is perhaps consistent with the more variable changes in self-processing that seem to occur during psychedelics (Millière *et al*., 2018). Although this figure is meant to serve as an intuitive illustration, it is consistent with the fact that psychedelics are known to induce greater entropy in neural activity, which is further believed to correspond to increased phenomenological richness (Carhart-Harris *et al*., 2014).

These differences also raise an intriguing, albeit speculative possibility that deep meditation may prevent some of the classic psychedelic effects. Hallucinations as well as changes in cognition and emotion experienced in the psychedelic state imply altered deep temporal processing, and if meditation halts the construction of models based on past experience, then it may also reduce some forms of hallucination and distorted perception - particularly since psychedelics are thought to target the highest levels of the cortical hierarchy (5-HT$_{2A}$ seratonin receptors). A simple hypothesis is that classic psychedelic effects at higher levels of the hierarchy (e.g., that pertain to changes in *narrative* self-processing) would be reported to a lesser degree by experienced practitioners during meditation. There is some preliminary evidence for this idea. In a double-blind placebo controlled study, Smigielski *et al*. (2019) administered Psilocybin to experienced meditators on the fourth day of a meditation retreat. Using the well-known Five Dimensional Altered States of Consciousness scale (5D-ASC), the meditators exhibited some of the usual effects of the psychedelics. Notably however, no signficant effects were found on the Dread of Ego Dissolution dimension (items include, loss of thought control, negative derealization, and thought disorder), which is in contrast to the results of eight other experiments administering psilocybin to non-meditators (Studerus *et al*., 2011). If the meditator has halted much of high-level narrative processing, then indeed any effects related to thinking ought to be diminished[17].

Providing an interesting anecdote, the late Richard Alpert (known as Ram Dass) and former Harvard Professor who assisted in the famous Good Friday LSD experiments - the first controlled double-blind study of its kind - reported giving an extremely high dose of LSD to his meditation teacher in India (Dass, 2010). On two occasions, he watched as the "Guru" (Neem Karoli Baba) ingested approximately 900 and then 1200 micrograms of LSD - up to ten times a normal dose - and appeared to show no effects, eventually asking if Alpert "...had anything stronger" (Dass, 2014). The recent renaissance and rapid growth of research on both meditation (Van Dam *et al*., 2018) and psychedelics (Swanson, 2018), and their purported positive effects on mental health, make their interplay an exciting domain of future study, particularly as they relate to the ability of the mature mind to change.

6. Discussion

> "*The senses perceive the object, which then the mental consciousness instantly conceptualizes in a manner conditioned by all of our past experience, and superimposes this conceptualized version back onto the originally neutral data of our senses - all of this occurring so fast that we don't even notice the process, and are only left in the end with the mind's conceptual version of things that we take to be reality.*" (Thrangu, 2011)

Cognitive neuroscience is undergoing a kind of Gestalt switch, from an understanding of the brain as a vessel that 'drinks in' the world, to an organ that repeatedly regurgitates the world through predictions derived from the past. This view of experience - as deeply contrived through past conditioning - is remarkably similar to Buddhist ideas at the root of mindfulness-based interventions now popular in Western science, as the above quote illustrates. Moreover, the gradual breaking down of concepts in Buddhist meditation maps on strikingly well to the gradual building up of a concept in the brain.

Previous research has often focused on how meditation can improve functioning in one way or another, including stress reduction, cognitive performance, or emotion regulation (Kabat-Zinn, 2003; Lutz *et al*., 2008a; Slagter *et al*., 2011b; Tang *et al*., 2015). However, many contemplative traditions from which these practices emerge suggest that meditation can go much deeper, focusing instead on understanding one's "true nature", "the nature of the self", or attaining certain insights about the nature of reality (Bodhi, 2011a; Suzuki, 1961; Wallace, 1999b)[18]. These seemingly esoteric aspects of meditation have been largely washed out of modern science perhaps for easier integration within a secular vision of mind, body, and brain. However, from the perspective of predictive processing, these facets of meditation suddenly become less mysterious and instead - we propose - the logical consequence of being truly "at one" with the present moment. That is, simply being present enough would naturally reduce abstract predictive modeling within the brain, and this in turn would naturally give rise to the phenomenology reported at various stages of practice.

More specifically, we have put forward the novel hypothesis that the habitual *modus operandi* of hierarchical predictive processing is progressively broken down by three main styles of meditation (FA, OM, and ND). We postulated that: (1) FA meditation reduces the precision and frequency of deep temporal models by up-weighting the precision of one input lower in the predictive hierarchy (e.g., the breath). (2) OM meditation further reduces counterfactual processing by reducing the frequency of predictions and balancing expected precision, thus permitting non-judgmental experiencing. Finally, (3) ND meditation creates the conditions for the final subject-object abstraction to fall away. In the ND state, all *expected*[19] error-minimization and thereby conceptualization (including self and time) ceases.

We also proposed in Section 4 (see also Figure 2) that FA, OM, and ND gradually abate the construction of self-processing at different levels of the predictive hierarchy, from the narrative self (i.e., thinking), to the embodied experiencing self (i.e., sensing), to non-self (i.e., awareness). We also showed how key insights - as targeted in classical Buddhism - can occur through meditation (Section 3.2). We proposed that reducing abstract processing in the predictive hierarchy may reveal certain insights about one's mind by increasing the transparency of predictive processes(e.g., discovering the impermanent or 'conditioned' nature of one's predictions as they are constructed and deconstructed). Further insights may arise through fact free learning (Friston *et al*., 2017) - the internal revision and refinement of models supported by the holistic non-action of meditation (i.e., *in-active* inference, Section 2.5). Below, we discuss the scientific value of meditation and outline important avenues for future research.

6.1 From Many to One: Novel insights from a unifying framework

There is a growing body of work investigating how meditation can change cognitive, emotional, and neural functioning (Dahl *et al*., 2015; Hölzel *et al*., 2011; Josipovic, 2014; Lutz *et al*., 2015b; Raffone *et al*., 2019; Vago & David, 2012; Vago & Zeidan, 2016). This work has also related specific styles of meditation to changes in predictive processing (Lutz *et al*., 2019; Pagnoni, 2019). Here, we extend this work by delineating how predictive processing may change from FA to OM to ND meditation, providing a unified account of meditation. Below we outline the scientific value of this new framework, with implications to our understanding of plasticity, psychopathology, rumination, and self. There are also several remaining outstanding questions in contemplative science (Van Dam *et al*., 2018) that our Many-to-One framework may specifically help address, including how meditation practice may induce enduring or trait changes in brain and mental functioning, how to determine meditation expertise, and how to approach negative meditation-related experiences.

6.1.1 The scientific value of meditation: Plasticity

It is not only interesting to know how meditation 'works' but also what meditation can teach us about the brain and mind. Clearly, such an intensive mental practice that can fundamentally shift perception and cognition may also be revealing about how the mind and the organ that gives rise to all mental activity, the brain, work. We have particularly suggested that meditation can be used as a tool to investigate the plasticity of brain and cognition by revealing what is amenable to change from within, and what is not. For instance, given at least preliminary evidence that meditation can modulate strong mental habits (see Section 5), then meditation could in turn be used to investigate which features of phenomenology are more or less engrained, thereby also informing theory in cognitive neuroscience. For instance, Yon *et al*. (2019) recently proposed that the sense of agency is a stubborn prediction, but as now suggested by multiple studies, the sense of agency can fall away during meditation (Dor-Ziderman *et al*., 2013, 2016; Lindahl & Britton, 2019; Metzinger, 2020). Meditation research may also be revealing regarding the processes that are most phylogenetically constrained in human beings: Some predictive processes may simply be too stubborn for any voluntary regulation. Nevertheless, it is important to keep an open mind since it is often very difficult to find and test multiple subjects who can reliably induce profoundly altered states during meditation, and very hard to determine who can do so a-priori. As contemplative science progresses valuable strides will perhaps occur when scientists are able to better establish expertise (see also 6.1.7) and gain access to highly advanced practitioners from a variety of different meditation traditions.

6.1.2 The scientific value of meditation: Psychopathology

Beyond brain plasticity, our framework can also shift the way we look at clinical outcomes. Meditation and mindfulness-based interventions show promise in treating depression, anxiety, stress, and more (Chiesa & Serretti, 2009; Hofmann *et al*., 2010). All such findings represent transformations in the way individuals construct their experience and behave in the world, and thus can be conceptualized as changes in predictive processing. Given our framework, clinical outcomes may conceivably follow from an initial deconstruction of problematic habits of prediction, and then a 'healthier' reemergence. This healthier reconstruction may be achieved particularly through model selection, optimization, and compression mechanisms (described in Section 2.5). Moreover, the inherently explorative nature of meditation - where the curious observation of all inner-experiences is strongly encouraged - may also serve the refinement of predictive modeling, and make perceptible hitherto ignored interoceptive, emotional, and cognitive processes (Schwartenbeck *et al*., 2019). Taken together, meditation may induce positive clinical outcomes by reducing habitual patterns of mental activity, revising stubborn habits and by increasing self-awareness.

6.1.3 The scientific value of meditation: Rumination

There may also be some further truths in the metaphor of '*pruning* the counterfactual tree'. It's obvious that excessive rumination is not conducive to a happy life (Killingsworth & Gilbert, 2010). Moreover, ruminative counterfactualizing seems to play a key role in the maintenance of psychopathologies such as anxiety and depression (Nolen-Hoeksema *et al*., 2008). We also earlier mentioned the tendency for humans to think about things that they are trying to avoid (Bulley *et al*., 2017) - what we called *anti-predictions* (e.g., "I don't want to get Alzheimer's disease"). Such ruminations may underlie substantial unnecessary mental turmoil and energy expenditure, as evidenced by the high metabolic demands of the DMN and links between rumination and negative mood states (Smallwood *et al*., 2009). Although rumination can have adaptive value when it is not excessive (Baird *et al*., 2012; Vago & Zeidan, 2016), *pruning* these high-level counterfactual cognitions through meditation may be one way to revise the immense multiplicity of thoughts to those that are adaptive to one's goals. Although meditation creates the potential for profound change, the nature of those changes also needs to be carefully and gently guided in constructive directions to mitigate harmful experiences (Britton, 2019). There are many meditation styles that are suited for this, for example compassion meditation, or loving kindness. These more 'constructive' practices (Dahl *et al*., 2015) may be important ingredients for guiding 'change' in a positive direction.

6.1.4 The scientific value of meditation: Self

Conducting experiments often require the manipulation of some variable. Therefore, in order to carry out rigorous experiments that are revealing about the nature of self-processing in the mind and brain scientists require ways to modulate it. Meditation is therefore obviously well placed as a tool for investigating the nature of the self, and relatively rare states of consciousness where self-processing either changes or entirely disappears. Both modern science and Eastern traditions of contemplative practice concur that the self is a kind of 'construct' that can breakdown or disappear under various conditions. Yet, science has gained most of its insights about the constructed nature of self-processing through clinical populations where such events can be highly debilitating and accompanied by several comorbidities and other symptoms. Meditation may uniquely permit the scientists to study the targeted modulation of specific self-processes constructed at various layers of the brain hierarchical system, and the changes to behavior, emotion, and phenomenology therein. The scientific study of ND meditation in particular may be crucial for better understanding the nature and neural basis of the so-called minimal phenomenal experience, consciousness without self-location in space, time representation or self-consciousness (or 'sciousness as William James termed it) (Metzinger, 2020). This state of awareness is currently not included in any major cognitive neuroscience theory of consciousness, yet, proposed by some to lie at the core of all conscious experiencing, as discussed above. Some expert ND meditators can allegedly reliably induce the non-dual state in laboratory settings, rendering this basic self-less awareness accessible to scientific investigation. Yet, as elaborated on below, this will require the development of novel methodological approaches.

6.1.5 The scientific value of meditation: Summary

Informed by our framework, we conclude that meditation has promise in expanding scientific frontiers by increasing our understanding of brain plasticity, the concomitants of psychopathology, as well as thinking and counterfactual cognition. Meditation is also well placed to help scientists address basic and fundamental questions for how the experience of an 'I' as an agent separate from a world 'out there' emerges from prediction-error minimization. There is also promise that meditation may unveil properties of consciousness itself, such as the possibility that there exists a state in which *only* consciousness remains, a kind of 'minimal phenomenal experience' (Metzinger, 2020), which raises the possibility of more targeted investigations of consciousness as such, rather than the experiences appearing through it. In the below, we outline how our framework can also push contemplative science to the next level by addressing outstanding questions in the scientific study of meditation.

6.1.6 Insights for contemplative science: From state to trait

As state-level meditation changes are known to lead to longer-term trait-level changes (Rael & Polich, 2006), one may also expect that meditators should display differential functioning of the predictive processing machinery 'off the cushion'. Drawing on our framework, more advanced meditators would be expected to naturally reside in a state where, over time, there is less abstract counterfactual cognition. This does not mean that a meditator is *incapable* of abstract processing, but that the habitual tendency to engage with deep temporal models ought to decrease, and be more easily attenuated. Indeed, there is fMRI evidence that meditators (regardless of tradition) may "...transform the resting state into one that resembles a meditative state" (Brewer *et al.*, 2011, p. 20255). Moreover, some well-known adepts of non-dual meditation have claimed that perceptions, sensations, and hence 'the world' does not exist for them, because the appearance of sensing and high-level thinking may be highly infrequent or barely noticeable (Maharshi, 2004; Nisargadatta, 1973). Long-term practice may hence also reduce the frequency of arising predictions in experience and their expected precision over time.

The transition of meditation from state to trait may also be driven by fact free learning and insight (Friston *et al.*, 2017). Meditation is a unique practice in the sense that it reduces typical active inference processes (including mental actions) and may thereby accelerate the revision or refinement of *existing* models. These revisions may then result in the development of new and potentially stable priors. Meditation experience could also render mental activity more counterfactually rich in the long term, as proposed by Pagnoni (2019). If meditation weakens ingrained prediction loops during practice, this would permit one to entertain a broader set of counterfactuals outside of formal meditation contexts. In other words, the broadscale loosening of beliefs may permit more flexibile and multidimensional processing (a prospect there is already some evidence for, Moore & Malinowski, 2009). In general, meditators should also experience less habitual grasping onto passing experience i.e., they should display a decrease of salience and stickiness of arising predictions (see for example, van Leeuwen *et al*., 2009). Thoughts and feelings may also become less self-related, which may foster an enduring sense of psychological well-being (Dambrun & Ricard, 2011).

6.1.7 Insights for contemplative science: Establishing expertise

Our model also has implications for what might constitute markers of meditation expertise. Currently, expertise in meditation is notoriously difficult to pin down and there has been much inconsistency on what counts as an experienced meditator in the literature (Van Dam *et al*., 2018). According to our account, meditative expertise could be partly captured by the extent to which the meditator is able to voluntarily modulate objective markers of stubborn predictions. For example, Antonova *et al*. (2015) found that startle habituation discriminated intensity of meditation practice better than self-report, dispositional, and practice-related measures. Thus, they proposed that habituation to the startle response could be used as an objective marker of expertise. We suggest that the startle response represents one of many possible objective markers of meditation expertise because it is a highly automatic response (i.e., a stubborn prediction). Many other measures could foreseeably be used, ideally in combination, to test whether a practitioner is able to enter states that are free from such habitual responses. Crucially, the more automatic the prediction, the more expertise would be required to prevent the habitual response.

To provide a few new directions for research on meditative depth, we suggest the following automatic responses are worthwhile investigating further, (1) implicit learning, statistical learning, and conditioning, (2) conceptual processing, such as the automatic formation of words from sounds, (3) visual illusions, such as perception of illusory shapes, and (4) the volitional modulation of wakefulness and arousal (Britton *et al*., 2014). Intriguingly, since many decisions and tasks require abstract, self, time, and space related processing, it is also possible that performance on some tasks would be *impaired* due to meditation. For example, while some mindfulness-based interventions might improve learning by enhancing the ability to focus attention (Laukkonen *et al*., 2020), other meditation practices may reduce the ability to learn and retain new information or extract statistical regularities. Indeed, a study in nonmeditators showed that individuals scoring high on self-reported mindfulness displayed impaired artificial grammar learning (Whitmarsh *et al*., 2013). Thus, meditation could also impede performance in some everyday life settings. Just as meditation may not always improve performance, it may not always lead to positive experiences.

6.1.8 Insights for contemplative science: Challenging experiences

Profoundly deconstructing the mind is not a simple and straightforward endeavor, and recent evidence suggests that negative and challenging experiences do occur and can be severe (Britton, 2019; Lindahl *et al*., 2017; Lindahl & Britton, 2019). Of particular relevance is a study conducted by Lindahl and Britton (2019) on changes to sense of self. They found that 72% of meditators - many of which were meditation teachers - reported experiencing changes to their sense of self as a consequence of practice, and 55% of these were accompanied by distress, and 45% with impairments in functioning. Changes to sense of self included changes to the narrative self, loss of ownership, loss of agency, changes to embodiment, changes to self-other or self-world boundaries, and the most debilitating experiences tended to accompany a loss of one's 'basic' self or sense of 'being'. Changes to the narrative self often occurred even during daily practice (33%), whereas the vast majority of more profound changes to one's basic embodied self happened while on a meditation retreat (93%). Under an 'emotion and attention regulation' view of meditation, such experiences seem surprising. However, within our framework, a deconstruction of self-related processing naturally arises from being immersed in the here and now, and changes to more basal forms of self-hood are expected with more prolonged and advanced practices, like those employed on meditation retreats. Thus, our framework is able to also account for the negative side effects of meditation, especially as they pertain to changes in self-related processing.

The prospect of severe negative side effects that outlast the actual meditation, including depersonalization and dissociation (Lindahl & Britton, 2019) certainly demands further research. One possibility drawn from our framework is that if during meditation one's sense of self does not fully abate, but instead is *partially* altered, this may then be experienced as distressing. Many aberrant experiences of self that may occur during for instance psychosis and schizophrenia, may indeed represent *changes* to self-modeling processes rather than the explicit *absence* that may arise through carefully guided meditation training. Similarly, as counterfactual processing is deconstructed and early layers of the predictive hierarchy become perceptible, what is discovered may not coincide (indeed strongly contradict) one's models at higher more abstract layers of the hierarchy, which may cause uncertainty and distress. Meditation thus may engender enormous prediction errors that can demand significant support and integration. As the popularity of meditation grows, more attention is needed within the secular meditation movement about the side-effects that practitioners may unwillingly encounter, and what 'priors' may be necessary to integrate surprising experiences in a healthy way. We stress that being present is not just an easy way to feel better but can in fact profoundly change how we view ourselves. Looking to the future, below we make specific recommendations for how to improve methodology in contemplative science to ensure balanced and accurate findings.

6.2 Methodological considerations

For the field of meditation research to grow into a mature field of science it has to address several methodological challenges (Davidson & Kaszniak, 2015; Slagter *et al.*, 2011; Van Dam *et al.*, 2018). First, meditation practice is inherently a subjective endeavor, and the number of hours of meditation experience does not necessarily indicate how advanced someone is in their practice. Thus, developing better methods to determine the quality of meditative states and track meditation experience is of utmost importance for understanding the physiological and psychological effects of meditation. Neurophenomenology, the combination of brain imaging with micro-phenomenology - detailed reports about one's mental experiences - provides one fruitful approach (Petitmengin *et al.*, 2019; Varela, 1996), as discussed above. But much further progress is still possible and necessary. It is particularly important that a systematic and validated set of first-person methods is developed, that is also specifically tailored towards different styles of meditation, but also treats them as lying on a continuum with partially overlapping effects. While the three styles of meditation are here proposed to lie on a continuum, gradually reducing the temporal depth of processing, their effects also greatly overlap. Present-moment awareness and dereification are for example likely higher during advanced states of FA than during novice OM states (Lutz *et al.*, 2015). In developing methods to track stages of meditation advancement, it is also very important to acknowledge that different meditation traditions may have different aims. For instance, classical Buddhism emphasizes insight into the three characteristics of experience: impermanence (aniccā), nonself (anattā), and suffering (dukkha). Thus, while we may be able to scientifically determine a meditators capability to enter 'deep states of meditation' based on our framework, what exactly constitutes "progress" is also determined uniquely by different meditation traditions and involves factors well beyond the meditation practice, such as ethical action. In general, researchers should be well aware of the many different meditation practices and Buddhist traditions that exist, and the historical context in which they developed (Dunne, 2015).

Another methodological challenge is that some very advanced meditative states may make it difficult to provide *any* useful self-reports whatsoever (during meditation or post-hoc) given the inherently non-conceptual nature of the meditation states. Moreover, one cannot ask meditators to engage in typical experimental tasks that require them to respond to stimuli during more advanced meditative states either, as this would automatically force them to engage in active inference. One promising approach that may reveal the neural basis of phenomenal experience during advanced meditative states without relying on reports is to combine so-called no-report paradigms with brain imaging (Tsuchiya *et al.*, 2015). Specifically, machine learning methods that utilize neural activity as *representational information*, for example multivariate pattern analysis or "decoding" techniques - in concert with the delivery of subtle or even pre-conscious stimuli through so-called no-report paradigms - could be used to learn more about advanced states of meditation that would otherwise be out of scientific reach, and their effects on predictive processing. Future studies should also include measurements of physiological activity, such as bodily arousal, that may critically change during meditation (Britton *et al.*, 2014; Metzinger, 2020).

Another major methodological challenge in the scientific study of meditation concerns the fact that participants cannot be blinded to the nature of the study (i.e., meditation) and hence may have certain expectations on how meditation should affect e.g., their cognitive performance that can (implicitly) bias results (i.e., the well-known placebo effect; Baskin *et al*., 2003). A recent study, for example, found that participants that were recruited using a suggestive flyer, advertising a "brain training and become smarter" study, scored 5 to 10 IQ points higher on an intelligence test after performing a 30-min cognitive "training" than participants that were recruited using a non-suggestive flyer that simply advertised a psychological study for monitory reimbursement (Foroughi *et al*., 2016). This example illustrates the profound effects that expectations can have on study outcomes. Participants in a meditation study may also be more motivated to do well because they believe meditation has positive effects or because they think the experimenter expects them to do well. It is therefore critical that meditation researchers try to control for these non-specific effects that can confound results by including active control groups. Active control groups could consist of experts in some other domain (e.g., athletes; Andreu *et al*., 2017) that are also invited to participate because of their specific expertise, or of participants that undergo a different intervention that is matched to the meditation intervention in the extent to which both the participants and teachers believe in the effectiveness of the intervention and on other important variables, such as number of contact hours (MacCoon *et al*., 2014). Another possibility is to use meditators as their own controls, for example, by comparing their brain activity or task performance during different states of meditation that are expected to induce differential effects (e.g., Josipovic *et al*., 2011; van Vugt & Slagter, 2014). This may also better control for potential pre-existing differences between expert meditators and controls, e.g., in sleep habits or personality characteristics.

Besides proper controls for non-specific effects, it will be important that the field of meditation research moves in the direction of a-priori specification of study predictions and analysis plans through preregistration, to counter experimenter biases during data collection and analysis. This is particularly important given that many meditation researchers are themselves meditators, and believe in the value of meditation. To summarize, despite much promise of meditation as a powerful intervention for neuro-cognitive change, and its potential contributions to science, progress critically depends on methodological rigor and the development of novel approaches that allow for more objective and/or non-intrusive assessment of the effects of meditation. Neurophenomenology and no-report paradigms in particular provide fruitful avenues for future research. Embracing Open Science is another important step towards scientific progress.

6.3 Conclusion

We have taken on the daunting task of providing a theory for understanding the effects of meditation within the predictive processing framework. Contemplative science is a young field and predictive processing is a new theory, although both have roots going much farther back. All theories are subject to change, but perhaps particularly so for such new domains of enquiry. Nevertheless, we think the conditions are suitable for a more overarching theory that may also thwart further siloing and fragmentation of scientific research, as has been commonplace among the mind-sciences. A strength of our framework is its simplicity: Being in the here and now reduces predictive processing. And yet, this basic idea can explain how each meditation technique uniquely deconstructs the minds tendency to project the past onto the present, how certain insights may arise, the nature of hierarchical self-processing, and the plasticity of the human mind. There is scope here, we think, to eventually reveal what makes a meditator an expert, why meditation has such broad clinical effects, and how we might begin mitigating some of the negative consequences of meditation. Last but not least, our framework seems to bring Eastern and Western ideas closer together, showing how first-person tools of contemplative enquiry can lead to similar viewpoints as the third-person tools of science.

Acknowledgements

This work was supported by an ERC starting grant (679399) to H.A.S. We would like to thank several colleagues and meditation teachers who provided insightful comments on our paper, including Henk Barendregt, Gregg Howard, Adam Bulley, Michiel van Elk, Aidan Lyon, and Yair Pinto. We also thank a colleague who wishes to remain anonymous for contributing to the ideas presented in this paper, but who is of the opinion that their ideas are misrepresented in the paper. Finally, we would like to thank Thomas Metzinger for valuable discussions on the topics addressed here.

Footnotes

1. Throughout this paper we use temporal depth, counterfactual depth, and abstraction, rather interchangeably. They are each different characteristics of hierarchically deep processing, and are often used interchangeably in the literature.
2. Here 'one' should be understood as 'not-two', or non-dual (i.e., one without the concept of one).
3. As the horticulturist shears away overgrown branches, meditation trims away the habitual conceptualization of experiences.
4. As soon as one is 'away' from the present moment, one has made an 'abstraction'. For example, there are the wavelengths of light that represent the shape of a 'teacup'. However, once it has been conceptualized *as a teacup* there is a new layer of abstraction that demands further inference from past experience than simply representing the wavelengths of light (i.e., more temporally deep processing). And yet, experiencing a 'tea cup' first necessitates the representation of the wavelengths of light contacting the retina (thus, hierarchical processing). Representing the teacup *then* permits further hierarchically deep processing: Such as recalling the time you drank green tea with brown rice kernels in a Japanese garden.
5. Autopoietic actions are those that allow an organism to reproduce, regenerate, and therefore maintain itself (Maturana & Varela, 1991).
6. Here we have already introduced many novel terms for readers new to predictive processing. By the time our theory is more concretely described these words should make much more sense.
7. The hidden word is 'introspection'
8. See Section 2.1: A hierarchy of expectations.
9. Evan Thompson (2020) has also argued that meditation involves the development of new concepts, such as 'moment-to-moment arising', 'not-self', and 'impermanence', concepts that then shape one's experience. From the perspective of fact-free learning, novel priors such as 'impermanence' may cast a simpler and more parsimonious account of the behavior of thoughts, feelings, and sensations, thereby reducing model complexity.
10. The non-dual state was also described early on in Western Psychology. In 1890 William James coined the term 'sciousness', which he described as an awareness preceding con-sciousness that is without subject or object (Bricklin, 2003). Other descriptions of non-duality are present in Hinduism as well as western neo-Platonic and Christian traditions. James also described an experience that has non-dual qualities as follows: "During the syncope, there is absolute psychic annihilation, the absence of all consciousness; then at the beginning of coming to, one has at a certain moment a vague, limitless, infinite feeling - a sense of existence in general without the least trace of a distinction between the me and the not-me." (James, 1890/1950, p. 273)
11. See also Ashtavakra Gita (Byrom, 1990 translation), perhaps the oldest non-dual text with Hindu origins.
12. Whether this is a genuine philosophical conundrum is questionable (certainly it's not inherently paradoxical that memories should form without selfhood, e.g., semantic memories). Moreover, it's possible that transition periods away-from and into non-dual states afford memory encoding.
13. Albahari (2009) proposes that the Eastern construct of witness-consciousness "captures the essence of subjectivity". The concept is originally derived from the contemplative tradition of Advaita Vedãnta, and was described as follows by Gupta (1998) in his book *The Disinterested Witness: A fragment of Advaita Vedānta Phenomenology*: "[it is] the basis for all knowing [but] different from the object known. It is implied in every act of knowing. It is the ultimate subject; it can never become an object of knowledge."
14. In Figure 3 we have used different layers of the hierarchy than Figure 2 in order to emphasize the behaviour of generative models. In lower layers in the hierarchy (i.e., "pure witnessing" or the subject/object divide shown in Figure 2) there is no longer phenomenology of sensory objects, and if there are, they are arising in later layers.
15. In the famous case of Ramana Maharshi, it is said that he was so absorbed in ND awareness that "...he was completely oblivious of his body and the world; insects chewed away portions of his legs, his body wasted away because he was rarely conscious enough to eat and his hair and fingernails grew to unmanageable lengths... [a return to a normal physical condition] was not completed for several years." (Godman, 2017). When he was discovered, food had to be placed in his mouth to prevent him from starving.
16. The Carter *et al*. (2005) findings also highlight the fact that very advanced FA practices may also be able to break down stubborn predictions. Indeed, it is believed that some practitioners are able to discover non-dual awareness through advanced FA, thus bypassing OM (Wallace, 1999b).
17. On the other hand, if a meditation practitioner is naturally embodying a more *experiencing* mode of self - but not yet in a non-dual state - then psychedelics may help to further deconstruct hierarchical processing in tandem with meditation. Consistent with this idea, the authors *did* find significant increases in Oceanic Boundlessness - a construct reminiscent of ND awareness - among meditators administered the psilocybin.
18. As noted by (Britton *et al*., 2014): "In his *Science and Buddhism: A Guide for the Perplexed*, Buddhist studies scholar Donald Lopez [(Lopez Jr, 2009)] laments "Where is the insistence that meditation is not intended to induce relaxation but rather a vital transformation of one's vision of reality?" Others warn how "a practice that only relaxes the mind might eventually prove harmful." [(Lutz *et al*., 2006)]"
19. As discussed in section 2.4 & 4, *expected* free-energy minimization involves predictions about states in the next moment (thus, counter-facts to the present moment, Friston, 2018).

Abstract

This article explores the notion that Freudian constructs may have neurobiological substrates. Specifically, we propose that Freud's descriptions of the primary and secondary processes are consistent with self-organized activity in hierarchical cortical systems and that his descriptions of the ego are consistent with the functions of the default-mode and its reciprocal exchanges with subordinate brain systems. This neurobiological account rests on a view of the brain as a hierarchical inference or Helmholtz machine. In this view, large-scale intrinsic networks occupy supraordinate levels of hierarchical brain systems that try to optimize their representation of the sensorium. This optimization has been formulated as minimizing a free-energy; a process that is formally similar to the treatment of energy in Freudian formulations. We substantiate this synthesis by showing that Freud's descriptions of the primary process are consistent with the phenomenology and neurophysiology of rapid eye movement sleep, the early and acute psychotic state, the aura of temporal lobe epilepsy and hallucinogenic drug states.

Keywords: freud; the ego; default-mode; prediction; free-energy

Abbreviations: BOLD = blood oxygen level dependent; DMN = default-mode network; fMRI = functional magnetic resonance imaging; REM = rapid eye movement

Introduction

In this synthesis we explore the notion that Freudian constructs may have real neurobiological substrates and could be usefully revisited in the context of modern neuroscience. It is worth noting that Freud had a formal training in neuroanatomy and was influenced by people like Helmholtz, who laid many of the foundations for theoretical neurobiology. Advances in empirical and theoretical neuroscience now allow us to recast some central Freudian ideas in a mechanistic and biologically informed fashion. Specifically, we note that the psychoanalytic distinction between the primary and secondary processes (as functions of the id and ego respectively) fit comfortably with modern notions of functional brain architecture, at both a computational and neurophysiological level. Although this may seem a rather abstract and ambitious synthesis, there is in fact an enormous amount of empirical evidence from neuropsychology, neuroimaging and psychopharmacology to support it.

In what follows we attempt to demonstrate consistencies between key Freudian ideas and recent perspectives on global brain function that have emerged in imaging and theoretical neuroscience. The intention is to demonstrate and develop the *construct validity* of the Freudian concepts. This should allow Freudian concepts to be operationalized and measured empirically and could enable a dialogue between psychoanalysts and neurobiologists. This may have implications for psychiatry to the extent that mechanistic theories of psychopathology appeal to either neurobiological or psychoanalytical constructs. We start by summarizing the key elements of the three areas that we want to relate to each other; namely the central Freudian constructs, the Helmholtzian or Bayesian brain framework and empirical findings from neuroimaging on the global organization of brain activity.

The primary and secondary process

Freud came to a realization that there are two fundamentally different modes of cognition (the primary and secondary process) through a study of 'altered' or 'non-ordinary' states of consciousness (e.g. Q115, Q333 and Q462 in Supplementary material). He recognized in certain non-ordinary states (e.g. dreaming and psychosis) a *mode of cognition* that is characterized by a primitive, animistic style of thinking. Freud conjectured that the exchange of neuronal energy is relatively 'free' in this mode and he named this the 'primary process'. Simultaneously, Freud recognized in non-ordinary states the loss of certain functions, which are normally present in waking cognition. He ascribed these functions to a central organization (the ego) which works to minimize the mind's free-energy. Freud named this function the 'secondary process' and defined its aim as one of converting 'free energy' into 'bound energy' (for a more thorough discussion of these central concepts of Freudian theory see the supporting quotes in the online Supplementary material, cited in Table 1):

> We seem to recognize that nervous or psychical energy occurs in two forms, one freely mobile and another, by comparison, bound; we speak of [activations] and [hyperactivations] of psychical material, and even venture to suppose a [hyperactivation] brings about a kind of synthesis of different processes - a synthesis in the course of which free energy is transformed into bound energy ...We hold firmly to the view that the distinction between the [primary] and the [secondary] state lies in dynamic relations of this kind, which would explain how it is that, whether spontaneously or with our assistance, the one can be changed into the other ... We have found that processes in the unconscious or in the id obey different laws from those in the ego. We name these laws in their totality the primary process, in contrast to the secondary process which governs the course of events in the ego. (Q461, Freud, 1940)

Table 1. **List of quotations pertaining to the characteristics of the secondary process (and the ego) and primary process thinking (and the id)**

The ego and the secondary process	**Relevant quotations from Freud**
1. Default energy store or reservoir, which possesses the property of being spontaneously or tonically active.	Q5, Q15, Q109, Q154, Q162, Q209, Q273, Q298, Q300, Q301, Q314, Q320, Q321, Q416, Q438, Q454
2. Receives and 'contains' or 'represses' endogenous excitation.	Q1, Q15, Q46, Q80, Q132, Q152, Q154, Q183, Q205, Q209, Q212, Q219, Q283, Q283, Q287, Q328, Q358, Q363, Q391, Q392, Q427, Q427, Q429, Q437, Q448, Q475
3. Minimizes free-energy.	Q2, Q8, Q18, Q70, Q199, Q200, Q283, Q285, Q307, Q314, Q321, Q366, Q373, Q410, Q461, Q483
4. Integrates or binds the primary process and its representational system (the id) into a broader, more cohesive, composite organization (the ego).	Q15, Q29, Q45, Q46, Q154, Q209, Q218, Q231, Q233, Q234, Q237, Q300, Q302, Q308, Q314, Q315, Q334, Q339, Q351, Q358, Q360, Q383, Q384, Q385, Q391, Q397, Q402, Q413, Q429, Q447, Q461, Q483
5. Specific ontogenetic development.	Q47, Q113, Q174, Q273, Q300, Q301, Q358, Q414, Q440, Q459, Q486
6. Supports reality-testing and perceptual processing.	Q15, Q19, Q23, Q39, Q51, Q153, Q234, Q258, Q259, Q310, Q350, Q356, Q363, Q373, Q375, Q380, Q392, Q427, Q428, Q429, Q448, Q482, Q485
7. Supports conscious awareness, cognition and directed attention.	Q10, Q21, Q27, Q39, Q40, Q153, Q154, Q204, Q234, Q238, Q249, Q254, Q334, Q372, Q380, Q427
8. Possesses internally and externally-focused components, which are inversely related (anti-correlated).	Q6, Q39, Q162, Q173, Q204, Q243, Q273, Q289, Q300, Q301, Q320, Q329, Q363, Q438, Q448, Q454, Q484
9. Excessive-engagement of internally-focused component and impoverished engagement of externally-focused network during pathological withdrawal; e.g. in depression and schizophrenia.	Q144, Q147, Q158, Q161, Q168, Q169, Q170, Q172, Q244, Q252, Q253, Q263, Q265, Q266, Q267, Q277, Q288, Q292, Q293, Q297, Q301, Q329, Q330, Q368,
10. Failure of systems to minimize free-energy (suppress endogenous excitation) results in disturbed affect, cognition and perception; as seen in non-ordinary states such as dreaming and psychosis.	Q23, Q35, Q58, Q115, Q134, Q135, Q147, Q231, Q261, Q262, Q333, Q365, Q383, Q455, Q462, Q466, Q469, Q475, Q476, Q482, Q485
The id and primary process thinking	**Relevant quotations from Freud**
11. Characteristics of the system unconscious/the id and primary process thinking: i.e. a primitive, 'magical' or animisitic style of thinking, characterized neurophysiologically by 'free' movement of energy. One can think of primary process thinking in evolutionary terms as a 'protoconsciousness'.	Q58, Q63, Q90, Q92, Q97, Q115, Q135, Q151, Q160, Q171, Q198, Q201, Q203, Q209, Q211, Q216, Q217, Q218, Q228, Q229, Q230, Q231, Q233, Q237, Q241, Q242, Q247, Q249, Q254, Q257, Q261, Q270, Q279, Q280, Q282, Q299, Q305, Q311, Q315, Q335, Q359, Q388, Q389, Q396, Q397, Q423, Q424, Q425, Q426, Q437, Q440, Q442, Q443, Q446, Q453, Q461, Q465, Q467, Q468, Q470, Q471, Q472, Q474, Q477, Q479, Q480, Q482, Q490, Q491

The quotations can be found in Supplementary material.

Free-energy and the Bayesian brain

In terms of theoretical and computational neuroscience, we will focus on Helmholtz's suggestion that the brain is an inference machine (Helmholtz, 1866; Dayan *et al*., 1995); this idea is now a fundamental premise in neurobiology (Gregory, 1968). Key examples of this include the Bayesian brain (Knill and Pouget, 2004), predictive-coding (Rao and Ballard, 1998) and the free-energy principle (Friston, 2009). This framework assumes that the brain uses internal hierarchical models to predict its sensory input and suggests that neuronal activity (and synaptic connections) try to minimize the ensuing prediction-error or (Helmholtz) free-energy. This free-energy is a measure of surprise and is essentially the amount of prediction-error. It is an information theory quantity that, mathematically, plays the same role as free-energy in statistical thermodynamics. Free-energy is not an abstract concept; it can be quantified easily and is used routinely in modelling empirical data (Friston *et al*., 2007) and in neuronal simulations of perception and action (Friston *et al*., 2009).

The notion of a hierarchy is central here because it allows the brain to construct its own top-down prior expectations about sensory samples from the world. This resolves one of the key challenges facing the brain and also allows it to resolve ambiguities when inferring and representing the causes of exteroceptive and interoceptive sensations. Crucially, the hierarchical form of internal models (and associated neuroanatomy) (Felleman and Van Essen, 1991) entails a progression in the complexity of representations, as one proceeds up the hierarchy from thalamic nuclei and primary sensory cortex to association and paralimbic cortex (e.g. from sensations, through perceptions to concepts). This progression is reflected in the temporal extent of what is represented; with higher levels representing extended sequences of events that best account for the stream of sensory information represented in lower levels (see Kiebel *et al*., 2008 for a full discussion and simulations).

The hierarchical architecture may also accommodate the distinction between the Freudian primary and secondary processes, where the secondary process provides top-down predictions to reduce free-energy associated with the primary process (*cf*. converting free energy into bound energy). Under this mapping between Freudian and Helmholtzian models, one can link the energy associated with the primary process and the free-energy of Bayesian formulations. In both accounts, higher cortical areas are trying to organize activity in lower-levels through suppression of their free-energy.

Intrinsic brain networks and the default mode

Analyses of spontaneous fluctuations in the blood oxygen level dependent (BOLD) signal of functional magnetic resonance imaging (fMRI) during unconstrained 'resting' states (typically lying quietly with eyes closed or fixating on a cross) have identified a number of large-scale intrinsic networks (Beckmann *et al*., 2005; Damoiseaux *et al*., 2006). Of particular interest here is the so called 'default-mode network' (DMN), a network of regions that show high metabolic activity and blood flow at rest but which deactivate during goal-directed cognition (Raichle, 2001). Recent work has confirmed that the major nodes of the DMN are functionally and structurally connected (van den Heuvel *et al*., 2008; Greicius *et al*., 2009) and that this connectivity develops through ontogeny (Fair *et al*., 2008; Kelly *et al*., 2009). Another feature of the DMN is the inverse relationship of its neuronal activity with that of another large-scale intrinsic network; the 'attention system' (Fox *et al*., 2005; Fransson, 2005; Corbetta and Shulman, 2002). In this article, we pursue the idea that these intrinsic networks correspond to the high-levels of an inferential hierarchy, which function to suppress the free-energy of lower levels (i.e. suppress prediction errors with top-down predictions). We associate this optimization process with the secondary process. Furthermore, we associate failures of top-down control with non-ordinary states of consciousness, such as early and acute psychosis, the temporal-lobe aura, dreaming and hallucinogenic drug states. In what follows, we organize the evidence that speaks to the integration of neurobiological and psychoanalytic ideas and conclude with a defence of its value and potential utility.

This article comprises three sections: in the first, we review evidence that the development and functioning of the DMN is consistent with ego-functions and the secondary process. We focus specifically on the DMN's containment of endogenous excitation and its suppression of systems engaged by exogenous stimuli. In the second, we review evidence that a loss of top-down control over limbic activity in hierarchically lower systems is equivalent to a loss of the ego's control over the primary process. In the final section, we discuss the clinical relevance of these ideas.

Large-scale intrinsic networks, the secondary process and ego

In this section, we introduce the idea that Freud's descriptions of the development and functioning of the ego resonate with the development and functioning of the DMN and its reciprocal exchanges with subordinate brain systems. Freud's first useful account of the ego was given in his posthumously published *Project for a Scientific Psychology* (Freud, 1895). Inspired by the recent introduction of 'neurone theory' by Cajal and Waldeyer-Harz, Freud hypothesized three functionally-distinct classes of neurone: the 'w neurones', which receive endogenous input and make up the ego; the 'neurones', which are sensitive to exogenous input; and the 'ω neurones', which signal qualitative information. Although this neuronal classification system was abandoned by Freud soon after its conception, the ideas that inspired it remained a source of influence throughout his work. Several of Freud's most important ideas were introduced and/or developed in the *Project*, including the notion that the ego is an organization that receives and contains/represses bottom-up endogenous excitation (Table 1, row 2; Q1, Q15, Q46 and Q429).

The secondary process, or 'secondary process cognition', is the mode of cognition of the ego; put simply, it is the mode of normal waking consciousness of adult humans (e.g. Q317). Freud described the secondary process as 'inhibited' and 'bound'; in contradistinction to the primary process which is 'free' and 'motile' (Freud, 1895, 1900). The concept of 'bound' energy was attributed by Freud to ideas first expressed by Breuer in their *Studies on Hysteria* (Breuer and Freud, 1895). Breuer conjectured the existence of a system of tonically active neurons, forming a 'reservoir of nervous tension' (e.g. Q45, Q154 and Q233). It is significant that the primary and secondary processes owe their inception to observations of non-ordinary states of consciousness (e.g. row 10, Table 1; Q23, Q35, Q115, Q333 and Q462). We shall see later that compelling evidence for the existence of two distinct modes of cognition can be found in studies of non-ordinary states. In what follows, we review the functional anatomy of the default-mode and related networks and then consider these networks from a theoretical perspective.

Functional anatomy of the default-mode

The notion of the DMN originated in a paper by Marcus Raichle reviewing a pattern of blood flow, glucose metabolism and oxygen consumption in the resting-state, which consistently decreases during goal-directed cognition (Raichle, 2001); in other words, a high-level distributed system whose activity is reciprocally related to the activity in cortical areas subserving task or stimulus-bound processing. Raichle proposed that this pattern reflects a default mode of brain function and a functionally relevant physiological baseline (Raichle, 2001). Subsequent work has associated activity in the network identified by Raichle and others (Greicius *et al*., 2003; Beckmann *et al*., 2005; Damoiseaux *et al*., 2006; Fransson and Marrelec, 2008; Wu *et al*., 2009) with phenomena such as self-referential processing, autobiographical recollection, mind-wandering and theory-of-mind (Gusnard *et al*., 2001; Vincent *et al*., 2006; Mason *et al*., 2007; Buckner *et al*., 2008; see also Q332).

Regions specifically implicated in the DMN include the medial prefrontal cortex, the posterior cingulate cortex, the inferior parietal lobule, the lateral and inferior temporal cortex and the medial temporal lobes (Buckner *et al*., 2008; Fransson and Marrelec, 2008). Analyses of resting-state functional connectivity and diffusion tensor imaging have showed that the major nodes of the DMN are strongly interconnected (Greicius *et al*., 2003, 2009; Van den Heuvel *et al*., 2009) and that this connectivity matures through development (Fair *et al*., 2008; Kelly *et al*., 2009). Functional connectivity in the DMN is relatively weak in the elderly (Andrews-Hanna *et al*., 2007; Damoiseaux *et al*., 2008) and in patients with attention deficit disorder (Castellanos *et al*., 2008) and impulse control disorders (Church *et al*., 2009). Interestingly, medial prefrontal cortex-posterior cingulate cortex connectivity is entirely absent in infants (Fransson *et al*., 2007). These findings imply that the DMN develops through ontogeny, in a manner that parallels the emergence of ego-functions (Table 1, row 5).

Model and data-driven analyses of resting-state functional connectivity, diffusion tensor imaging analyses of structural connectivity and anatomical work in primates suggest that the medial temporal lobes are connected to the medial prefrontal cortex and posterior cingulate cortex nodes of the DMN (Catani *et al*., 2003; Vincent *et al.*, 2006; Buckner *et al.*, 2008; Fransson and Marrelec, 2008; Kahn *et al.*, 2008; Saleem *et al.*, 2008; van den Heuvel *et al.*, 2008; Robinson *et al.*, 2009). This is important because the medial temporal lobes contain key structures (e.g. the hippocampal formation, the amygdala, parahippocampal gyrus and entorhinal cortex) that play a role in mnemonic and hedonic or emotional processing. The evidence suggests that medial prefrontal cortex-medial temporal lobe functional and structural connectivity increases through ontogeny (Eluvathingal *et al.*, 2007; Kelly *et al.*, 2009) with a notable increase at puberty (Benes *et al.*, 1989). A recent study found reduced medial prefrontal cortex-amygdala functional connectivity in patients with schizophrenia and an inverse correlation between connectivity and aggression in these patients (Hoptman *et al.*, 2009). Preclinical work indicates that emotional extinction takes place via glutamatergic projections from the medial prefrontal cortex terminating on inhibitory interneurons in the medial temporal lobes (Rosenkranz and Grace, 2002; Rosenkranz *et al.*, 2003) and a recent analysis of effective connectivity implied that activation of the rostral anterior cingulate drives inhibition of the amygdala in response to fearful faces (Stein *et al.*, 2007).

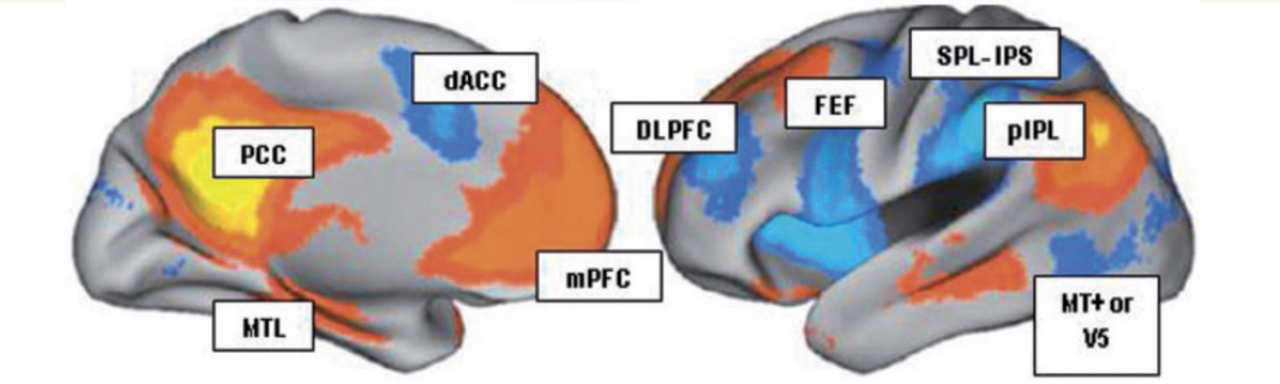

Figure 1 The DMN (yellow/orange) and attention system (blue): resting state functional connectivity of three seed regions: the dorsal medial prefrontal cortex, ventral medial prefrontal cortex and hippocampal formation (medial temporal lobes). Positive correlations (yellow-orange) with all seeds were evident in the posterior cingulate (PCC), posterior inferior parietal lobule (pIPL) and medial prefrontal cortex (mPFC). Regions negatively correlated with these seeds constitute the attention system and include the superior parietal lobule (SPL), intraparietal sulcus (IPS), the motion-sensitive middle temporal area (MT+), the frontal eye fields (FEF) the dorsal anterior cingulate (dACC), the dorsolateral prefrontal cortex (DLPFC), the ventral premotor cortex and the frontal operculum. Image reproduced from Buckner *et al.* (2008), with permission.

There is a huge amount of clinical and preclinical evidence supporting the limbic-suppressive function of the medial prefrontal cortex (Hariri *et al.*, 2000; Milad and Quirk, 2002; Rosenkranz and Grace 2002; Phillips *et al.*, 2003; Phelps *et al.*, 2004; Etkin *et al.*, 2006; Milad *et al.*, 2006). Functional neuroimaging studies have correlated primitive thought and emotion with decreased activity in the medial prefrontal cortex and increased activity in the medial temporal lobes (Pietrini *et al.*, 2000; Dougherty *et al.*, 2004), while suppression of these behaviours correlated with medial prefrontal cortex activations (Pietrini *et al.*, 2000; Beauregard *et al.*, 2001; Dougherty *et al.*, 2004). The recollection of distressing memories and emotions in patients with post-traumatic stress disorder has also been found to correlate with medial prefrontal cortex deactivations and medial temporal lobe activations (Bremner *et al.*, 1999; Shin *et al.*, 2004, 2006; Hopper *et al.*, 2007) and the blockade of these memories also correlated with medial prefrontal cortex activations (Lanius *et al.*, 2002; Reinders *et al.*, 2003, 2006). Damage to the ventromedial prefrontal cortex has long been associated with impaired impulse control (Grafmen *et al.*, 1996; Anderson *et al.*, 1999; Davidson *et al.*, 2000; Kaplan-Solms and Solms, 2001; Solms and Turnbull, 2002). The medial prefrontal cortex sends dense projections to the ventral striatum (Ferry *et al.*, 2000) and midbrain (Carr and Sesack, 2000). The ventral striatum displays functional connectivity with the midbrain, medial temporal lobes and higher-level nodes of the DMN (Postuma and Dagher, 2006; Di Martino *et al.*, 2008; Gutman *et al.*, 2009) and the midbrain and ventral striatum signal prediction-error and motivational-salience (Robbins and Everitt, 1996; Berridge and Robinson, 1998; Schultz, 2002; Kapur, 2005). In summary, the DMN comprises high-level cortical nodes such as the medial prefrontal cortex that exchange neuronal signals with subcortical systems and other association and polymodal cortex, especially the systems responsible for emotional learning and memory. Much of the evidence suggests that activation of the DMN suppresses activity in lower systems. We now consider these aspects of functional anatomy in the light of hierarchical inference and the secondary process.

Theoretical formulations of the default mode

Freud argued that the ego modulates both endogenous and exogenous excitation. Empirically, this can be seen in early and acute psychosis, the aura of temporal lobe epilepsy and hallucinogenic states, where affective (e.g. fear), mnemonic (e.g. moments of déjà vu or vivid recollection), perceptual (e.g. hallucinations) and cognitive (e.g. confused or muddled thinking) processing is perturbed (Bleuler, 1911; Epstein and Ervin, 1956; Cohen, 1964; Vollenweider *et al.*, 1997) (Table 1, row 10; e.g. Q462). He further hypothesized that the ontogenetic/phylogenetic evolution of healthy, adult waking cognition depends on the formation of an equilibrium between the pressing forces of the primary process (entailed by the id) and the counter forces of the secondary process (entailed by the ego) (e.g. Q116). This description is remarkably consistent with contemporary models of cognition based on hierarchical Bayesian inference and Helmholtzian free-energy; where backward connections from higher cortical areas work to minimize the free-energy of lower areas (Mumford, 1992; Rao and Ballard, 1999; Friston, 2003; Kiebel *et al.*, 2009).

Anatomically speaking, forward connections originate in supragranular layers and terminate in layer four spiny stellate cells. They project from lower to higher-levels; e.g. from thalamic nuclei to primary sensory cortex or from secondary sensory cortex to tertiary sensory areas. Backward connections are more abundant and diffuse than forward connections and their effects are primarily modulatory. Backward connections originate in deep pyramidal cells (infragranular layers) of the cortex and target infra and supragranular layers of lower cortical areas. Based on Bayesian and Helmholtzian principles it has been proposed that forward connections convey prediction-errors that optimize representations in higher levels. These representations are then used to form predictions that are conveyed by backward connections to lower levels. These predictions suppress or cancel prediction-errors (free-energy) until they can be minimized no further (Friston, 2003, 2005). In this way, the brain optimizes its representation of the world by suppressing prediction-errors with reciprocal message passing between hierarchical levels to minimize free-energy. This suppression simply involves countering excitatory presynaptic inputs (from representational units to neurons encoding prediction-error) with top-down presynaptic inputs, mediated by inhibitory interneurons. When the representations at any level can be explained by top-down predictions from the level above, prediction-error is minimized and the representations are internally consistent over levels. The aim of this process is to optimize parsimonious explanations for what caused sensory input (Friston, 2003) and establish sensory predictions to guide action and behaviour (Friston *et al.*, 2009). Crucially, this empirically-informed scheme (Sandell and Schiller, 1982; Girard and Bullier, 1989; Hupé *et al.*, 1998; Kleinschmidt *et al.*, 1998; Murray *et al.*, 2002; Lachaux *et al.*, 2005; Chen *et al.*, 2008) recapitulates Freud's 19th century conception and in particular his *principle of constancy*:

> [We] have taken the view that the principle which governs all mental processes is a special case of Fechner's "tendency towards stability", and have accordingly attributed to the mental apparatus the purpose of reducing to nothing, or at least of keeping as low as possible, the sums of excitation which flow in upon it. (Freud, 1924; Q366)

It is significant that Freud cited as his inspiration for these ideas, Gustav Fechner, the founder of psychophysics and a contemporary of Helmholtz (e.g. Q307, Q353, Q366, Q379): the process of minimizing 'the sums of excitation' is exactly the same as minimizing the sum of squared prediction-error or free-energy in Helmholtzian schemes. This rests on the assumption that the brain explicitly encodes prediction-error with neuronal activity (excitation) that is suppressed or explained by backward (top-down) afferents.

As mentioned above, Freud argued that the ego modulates and suppresses both exogenous and endogenous signals (Table 1, rows 2 and 6). In neurobiological terms, exogenous signals correspond to interoceptive and exteroceptive signals from thalamic and unimodal sensory areas that convey sensory signals (predictionerrors) to polymodal and medial temporal lobe structures. Endogenous signals could be equated with subsequent bottom-up prediction errors (excitation) arising in limbic and paralimbic systems, which are passed up to high-level polymodal cortical areas that comprise the nodes of the default-mode.

Clearly, the principles that attend hierarchical inference under Helmholtzian schemes are generic and may apply to all hierarchically deployed brain systems. However, we will focus on the DMN; specifically, on medial prefrontal suppression of limbic and paralimbic activity, and associate this with the suppression of endogenous activity by the ego. We now consider how the ego modulates excitation evoked by stimuli from the external world.

Hierarchical brain systems

As discussed in the introduction, BOLD signal oscillations in the DMN are characterized by their inverse relation to those of another major intrinsic network, referred to as the attention system (Corbetta and Shulman, 2002; Fox *et al*., 2005; Fransson, 2005). As well as showing a spontaneous inverse relationship with the DMN, the attention system is activated during externally-directed cognition and deactivated during internally-directed cognition, whereas the opposite is true of the DMN (Buckner *et al*., 2008); implying a 'give-and-take' relationship (Raichle, 2009). Regions implicated in the attention system include the dorsolateral prefrontal cortex, the dorsal anterior cingulate cortex, the frontal eye fields, the extrastriate cortex (e.g. V5) the superior parietal lobule, the intraparietal sulcus and the ventral premotor cortex (Buckner *et al*., 2008). These regions are active during target detection, attention to spatial detail and hand-eye coordination (Corbetta and Shulman, 2002; Shulman, 2003). Moreover, many of these nodes have been associated with top-down control of primary sensory input (Friston and Büchel, 2000; Lachaux *et al*., 2005). High-level association cortices not only receive feedforward signals from sensory regions but also anticipate and reciprocate these inputs with backward connections conferring context-specificity and higher-level constraints (i.e. predictions) (Rao and Ballard, 1999; Friston, 2003, 2005; Angelucci and Bressloff, 2006).

Recent work has suggested that what we have referred to as the 'attention system' is in fact not a unified system. Based on independent component analyses of resting state BOLD activity, Seeley *et al*. (2007) have shown that the system described by Fox *et al*. (2005) and Fransson (2005) can be differentiated into a 'salience system' which includes the dorsal anterior cingulate cortex, frontoinsular cortices, amygdala and ventral midbrain; and a more dorsal and lateral cortical system (the 'dorsal attention system') which includes the dorsolateral prefrontal cortex, frontal eye fields, dorsal medial prefrontal cortex, intraparietal sulcus and superior parietal lobule. BOLD signal oscillations in both systems exhibit an inverse relationship with those in the posterior cingulate cortex of the DMN (Greicius *et al*., 2003) but the systems do not appear to be well integrated with each other. This differentiation has also been suggested by others (He *et al*., 2007; Dosenbach *et al*., 2008; Sridharan *et al*., 2008; Vincent *et al*., 2008).

The picture that emerges is of a hierarchy of brain systems with the DMN at the top and the salience and dorsal attention systems at intermediate levels, above thalamic and unimodal sensory cortex. Under a Helmholtzian model, each system is trying to suppress the free-energy of its subordinates, through a process of optimizing predictions to reduce prediction-errors. This rests on recurrent message-passing between these systems that leads to self-organized activation patterns with a characteristic reciprocity or 'give-and-take' among levels. In this view, activation of the attention system may facilitate the suppression of exogenous excitation (Q258). Similarly, the DMN furnishes top-down control of the attentional and salience systems by explaining and thereby suppressing their activity. We next address the physiological basis of message-passing or interactions among brain regions that mediate this self-organized suppression.

Spontaneous BOLD oscillations and neuronal activity

Until recently, there had been some uncertainty about whether spontaneous BOLD-signal oscillations are generated by neuronal activity or non-neuronal physiological processes (Wise *et al*., 2004; Birn *et al*., 2006). Recent work has shown that spontaneous BOLD oscillations most probably have a neuronal origin (He *et al*., 2008; Nir *et al*., 2008; Shmuel and Leopold, 2008). Simultaneous fMRI and intracranial recordings in monkeys (Shmuel and Leopold, 2008) and humans (Nir *et al*., 2007) have identified spontaneous neuronal fluctuations that correlate with spontaneous BOLD fluctuations (Shmuel and Leopold, 2008). The neuronal fluctuations, which are coherent across the hemispheres, were evident in multiunit firing rates and local field potential gamma power. Stimulus evoked BOLD activations have also been shown to correlate positively with gamma power (Niessing *et al*., 2005). Gamma has been associated with attention, feature-binding and expectancy (Singer and Gray, 1995; Herrmann, 2000; Engel *et al*., 2001). This suggests that BOLD fluctuations reflect cortical coherence associated with gamma and secondary process cognition, particularly since the gamma frequency, recorded in higher-level cortical areas, has recently been shown to suppress lower frequencies in lower-level cortical areas (Chen *et al.*, 2009). This leads us to predict that the fluctuations in gamma power evident in the large-scale intrinsic networks index the ongoing minimization of free-energy in subordinate levels of the hierarchy (Engel *et al.*, 2001; Raichle, 2007) and could provide an empirical measure of the secondary process.

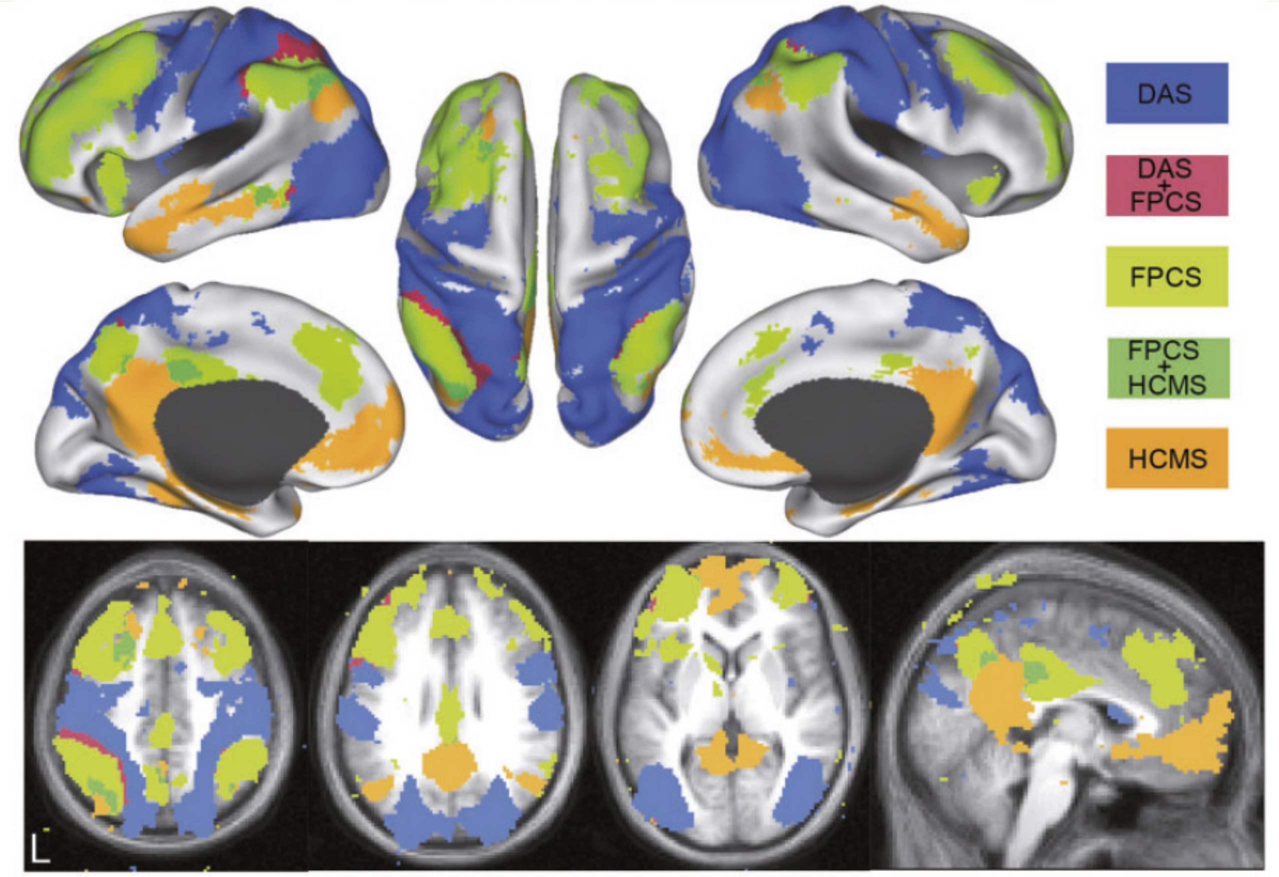

Figure 2 Resting state functional connectivity in three cortical networks: (i) dorsal attention system (DAS, blue) using voxels in the middle temporal area and superior parietal lobule as regions of interest; (ii) the salience system (light green) using voxels in the anterior PFC and anterior inferior parietal lobule as regions of interest; and (iii) the default mode network (orange) using the hippocampal formation and posterior inferior parietal lobule as regions of interest. Overlap between the networks is shown in dark green (salience system and DMN) and red (dorsal attention systems and salience system). Image used with permission from Justin Vincent and Randy Buckner.

Generally speaking, oscillatory processes are ubiquitous in the brain and serve to couple remote neuronal populations. High frequency gamma has often been implicated in perceptual synthesis and binding (e.g. Singer, 2009); while theta rhythms have been most studied in the hippocampal system, where they are associated with (spatial) memory and exploration (e.g. Lisman and Redish, 2009). Crucially, theta and gamma are themselves coupled (e.g. Sirota *et al.*, 2008), where slower theta oscillations may provide a temporal frame of reference for faster computations mediated at gamma frequencies. We will return to the oscillations and frequency-specific coupling in the brain in the next section.

So far we have discussed the importance of reciprocal or anti-correlated activity in the DMN and networks for goal-directed cognition. However, it should be noted that spontaneous fluctuations in the DMN continue during active cognition, just as spontaneous fluctuations in the dorsal attention system continue during rest (Hampson *et al.*, 2002; Beckmann *et al.*, 2005; Damoiseaux *et al.*, 2006; Fox *et al.*, 2007). This tonicity presumably primes structures to infer exogenous inputs (Fox *et al.*, 2007; Raichle, 2007) and supports a background level of predictive coding (Hampson *et al.*, 2002). Furthermore, spontaneous fluctuations in the BOLD signal, which can be as large in amplitude as evoked BOLD responses (Fox *et al.*, 2007), have been shown to reflect variations in behaviour (Boly *et al.*, 2007; Fox *et al.*, 2007). Much of the brain's vast energy budget is reserved for spontaneous neuronal activity (Fox and Raichle, 2007; Raichle, 2007). We speculate that spontaneous activity in the DMN reflects the constant containment of spontaneous endogenous activity - commensurate with Freud's concept of repression (Q209), while spontaneous activity in the dorsal attention system indexes the continual monitoring and suppression of exogenous stimuli. This conjecture appeals to the

Helmholtzian view of the brain as an inference engine that continually generates predictions and hypotheses that, when freed from the present (Kiebel *et al.*, 2009), necessarily entails the past and future.

In addition to the functional importance of spontaneous neuronal activity in intrinsic networks, the give-and-take between the default system and task-positive systems appears to be vital for active cognition and conscious awareness (Pomarol-Clotet *et al.*, 2008; He and Raichle, 2009; Whitfield-Gabrieli *et al.*, 2009). Functional connectivity within the DMN has been shown to increase through ontogeny (Fair *et al.*, 2008; Kelly *et al.*, 2009), decrease in ageing (Andrews-Hanna *et al.*, 2007; Damoiseaux *et al.*, 2008) and to be underdeveloped in patients with impaired impulse control (Church *et al.*, 2009). These findings imply that functional connectivity in the DMN (Hampson *et al.*, 2006) and the dorsal attention system (Seeley *et al.*, 2007) provides an index of cognitive aptitude but not necessarily *active cognition* (Larson-Prior *et al.*, 2009). Ineffective deactivation of the DMN has been associated with cognitive error in healthy subjects (Li *et al.*, 2007; Eichele *et al*. 2008) and negative symptoms in schizophrenia (Pomarol-Clotet *et al.*, 2008; Whitfield-Gabrieli *et al.*, 2009) and depression (Grimm *et al.*, 2009; Sheline *et al.*, 2009). Functional connectivity in the DMN is not significantly altered in sleep, sedation or coma (Boly *et al.*, 2008; Larson-Prior *et al.*, 2009) but the give-and-take between the DMN and its anti-correlated networks is (He and Raichle, 2009) (see Q238).

Summary and synthesis

In this section, the secondary process was considered in relation to large-scale intrinsic networks working to predict and suppress excitation (Helmholtz free-energy) in subordinate systems. The concept of the secondary process entailed by ego-functions was associated with the suppressive effect of the DMN on its subcortical nodes and anti-correlated networks. Functional connectivity between limbic (e.g. the hippocampus and amygdala) structures and major nodes of the DMN during rest (Buckner *et al.*, 2008; Di Martino *et al.*, 2008) supports the notion that the systems enacting ego-functions have evolved to receive and control endogenous excitation that underlies mnemonic and hedonic processing. In the next section, we focus on the primary process and specifically how it is manifest in non-ordinary states of consciousness.

The phenomenology of primary process thinking

In this section we describe the phenomenology of non-ordinary states of consciousness that have been associated with primary process thinking. The primary process is not generally regarded as a serious topic of science but the phenomenology of certain non-ordinary states compel us to consider its importance. Psychoanalysis owes its origins to observations of non-ordinary states (Table 1, row 10; e.g. Q23, Q35, Q115, Q333; Q462). An early observation that has remained at the core of the Freudian model is that there exists in the mind an archaic *mode of cognition*, which under normal waking conditions is effectively suppressed (Q315). Freud saw this 'primary' mode as belonging to an ontogenetically and phylogenetically primitive system, which he referred to initially as 'the unconscious' (Breuer and Freud, 1895), later as 'the system unconscious', 'system Ucs' or just 'Ucs' (Freud, 1900, 1915 b) and eventually as 'the it' (Freud, 1923) (note: Freud's original term for 'the id' was 'das es' and should really have been translated 'the it', just as his original term for 'the ego', 'das Ich', should have been translated 'the I'; for simplicity however, we will use the familiar terms 'id' and 'ego').

Thus, the term 'the id' was introduced relatively late by Freud (Freud, 1923) as a new name for 'the unconscious' in its systematic sense (i.e. 'the system unconscious' or 'system Ucs') (Freud, 1900, 1915 b). Freud wrote relatively less about the id than the system unconscious but the two are essentially synonymous (see Q422, Q423, Q458 and Q461). Freud's decision to rename the system unconscious 'the id' was motivated by his acknowledgement that aspects of the ego are also unconscious (in the descriptive sense) and processes in the id can become conscious. The introduction of the id was useful in this respect as it resolved ambiguities relating to the descriptive meaning of 'unconscious'. Referred to as 'the id', the unconscious could be understood more explicitly as a *system* subserving a specific *mode* of cognition (e.g. Q461).

The characteristics of primary process thinking are clearest when contrasted against those of the secondary process: just as the characteristics of the primary process only become manifest in certain non-ordinary states, the characteristics of the secondary process only really become evident when they are lost. For example, Freud considered timelessness to be a major characteristic of the id and time perception to be a function of the ego (e.g. Q424). The notion of timelessness is difficult to comprehend from the vantage of normal waking consciousness but becomes clearer if we consider the phenomenology of states such as the temporal lobe aura: 'Time seems endless' (Epstein and Ervin, 1956); acute psychosis: 'Time slowed down, much more experience could be crowded into a brief time span' (Bowers, 1965) and the hallucinogenic drug state: '[Under the influence of drugs such as LSD, one has] the feeling that *so much* was "seen" that "hours" or "days" or "aeons" must have passed' (Masters and Houston, 2000). Recent work involving the serotoninergic hallucinogen, psilocybin, has shown that hallucinogen-induced impairments in temporal perception are dose-dependent (Wackermann *et al.*, 2008). Furthermore, recent formulations of the free-energy principle suggest that there is a systematic increase in temporal coherence in higher-level structures (Kiebel *et al.*, 2009). Thus, impaired temporal perception is a property of primary process thinking that has the potential to be measured psychophysically; thus bringing previously intangible phenomena into the scientific realm. Four other qualities of primary process thinking that can be assessed empirically include the following.

i. Sensations of fear or dread, e.g. in the aura of temporal lobe epilepsy: 'I feel afraid, as if something awful might happen' (Williams, 1956); early psychosis: 'Suddenly Fear, agonizing, boundless, Fear, overcame me, not the usual uneasiness of unreality, but real fear, such as one knows at the approach of danger, of calamity' (Sechehaye, 1951); the hallucinogenic drug state: 'I found myself all at once on the brink of panic' (Huxley, 1954); and dreaming: 'Fear is the most frequently occurring dream emotion' (Bulkeley, 2009).
ii. Perceptual distortions/visual hallucinations, e.g. in the aura of temporal lobe epilepsy: 'The surroundings feel strange and unfamiliar' (Hansen and Brodtkorb, 2003); early psychosis: 'It wasn't really unreal; it was just strange, funny, different' (Cutting and Dunne, 1989); and the hallucinogenic drug state: 'The room and furniture were distorted, strange and terrifying' (LSD, Cohen, 1964).
iii. Déjàvu, recollective or reliving phenomena, e.g. in the aura of the temporal lobe epilepsy: 'I went back to all that occurred in my childhood' (Hughlings-Jackson, 1879); early psychosis: 'My whole world seemed to cave in - I kept thinking about my birthplace and my past' (Cutting and Dunne, 1989); and the hallucinogenic drug state: 'I started to cry uncontrollably and nothing could have stopped it - it was like a dam giving way. At first I didn't know what I was weeping about, but soon became aware that I was reliving childhood experiences of which I had scarcely any conscious knowledge. Until today I had remembered only fragments, but now the entire sequence reeled off as from a microfilm that was securely stored within my head' (LSD, Cohen, 1964).
iv. Disturbance to the sense-of-self, e.g. in the aura of temporal lobe epilepsy: 'I felt that I disappeared' (Johanson *et al.*, 2008); early psychosis: 'When I look at somebody my own personality is in danger. I am undergoing a transformation and myself is beginning to disappear' (Chapman, 1966); and the hallucinogenic drug state: 'I felt the relaxing of the self boundaries' (LSD, Cohen, 1964).

Other characteristics of primary process thinking include a fear of losing control of ones mind, a general sense of the peculiarity of things, euphoria, grandiosity, paranoia and suspiciousness, thought-disturbances, bizarre thought-content and an increased interest in mystical, magical or animistic notions. All these phenomena could easily be assessed using subjective rating scales as a global measure of ego-disturbance or primary process thinking. However, an association between the primary process and dreaming, acute psychosis, temporal lobe aura and hallucinogenic states can be motivated at a purely phenomenological level. Crucially, all these states have been compared with each other previously; e.g. psychosis and dreaming (Freud, 1900; Jung, 1907; Bleuler, 1911); psychosis and the temporal lobe aura (Slater and Beard, 1963; Bear, 1979; Ferguson and Rayport, 2006); psychosis and the hallucinogenic drug state (Behringer, 1927; Bowers and Freedman, 1966; Gouzoulis *et al.*, 1994); dreaming and the temporal lobe aura (Rodin *et al.*, 1955; Penfield and Perot, 1963; Mahl *et al.*, 1964); dreaming and the hallucinogenic drug state (Grof, 1975; Fischman, 1983; Callaway, 1988); and the temporal lobe aura and the hallucinogenic drug state (Bercel *et al.*, 1956; Schwarz *et al.*, 1965; Balestrieri, 1967). It is also worth noting that dreaming (Freud, 1900), psychosis (Freud, 1900; Bleuler, 1911), the temporal lobe aura (Kubie, 1952; Robin *et al.*, 1955; Delgado *et al.*, 1956; Epstein and Ervin, 1956; Ostow, 1957; Mahl *et al.*, 1964; Horowtiz *et al.*, 1968) and the hallucinogenic drug state (Busch and Johnson, 1950; Sandison *et al.*, 1954; Cattell, 1957; Martin, 1957; Eisner, 1959; Cohen, 1964; Abramson, 1967; Horowitz *et al.*, 1968; Grof, 1975) have all been described as states conducive to the emergence of primary process thinking. In the remainder of this section we will review evidence that these states, which clearly display a related phenomenology, also possess a related neurophysiology.

Neurophysiology of the primary process

In this section, we show that brain states associated with primary process thinking have common neurophysiological substrates. Intracranial electroencephalography (EEG) recordings in medial temporal structures, the superior temporal gyrus and the visual association cortex, after high-frequency stimulation of the perirhinal cortex, reveals bursts of synchronous high-amplitude theta activity spreading from the medial temporal lobes to the visual association cortices during the hallucinatory revival of past experiences (Barbeau *et al.*, 2005). This activity is consistent with Freud's speculations about the processes underlying dreaming and related states (e.g. Q97 and Q98). Similar activity has been recorded in the medial temporal lobes of other epileptic patients during states of hallucinosis and recollection (Rodin *et al.*, 1955; Heath, 1961; Stevens *et al.*, 1969) and increased theta power has been recorded over the medial temporal lobes during recollection using magnetoencephalography (Guderian and Düzel, 2005).

In the 1950s and early 1960s, activity was recorded in cortical and subcortical structures in a large number of patients experiencing acute psychotic episodes (Heath, 1954; Lesse *et al.*, 1955; Sem-Jacobsen *et al.*, 1956; Heath and Mickle, 1960; Sherwood, 1962; Heath and Walker, 1985). Subcortical contacts revealed conspicuous activities, which were generally not seen in the cortex or at the scalp (Sem-Jacobsen *et al.*, 1956; Heath and Mickle, 1960). In actively psychotic patients, spiking and bursts of high-amplitude synchronous activity (of variable frequency but often theta) were recorded in the septum (which until the mid-1970s included the nucleus accumbens) (Heath, 1954; Stevens, 1999) amygdala and hippocampus (Sem-Jacobsen *et al.*, 1956; Heath and Mickle, 1960; Sherwood, 1962). This activity was specific to these regions, was most pronounced when the psychosis was most florid and was absent when the symptoms remitted (Heath and Mickle, 1960).

Intracranial recordings in subjects administered the hallucinogenic drugs LSD and mescaline revealed spiking and bursts of high-amplitude activity in the medial temporal lobes similar to that recorded in the acutely psychotic patients (Schwarz *et al.*, 1956; Sem-Jacobsen *et al.*, 1956; Monroe *et al.*, 1957; Heath and Mickle, 1960; Chapman *et al.*, 1962). LSD and related drugs were used extensively in the 1950s and 60s as adjuncts to psychoanalytic psychotherapy (Abramson, 1967; Grinspoon and Bakalar, 1979). Spontaneous recollections of a similar nature to those associated with the temporal lobe aura (e.g. Penfield and Perot, 1963; Barbeau *et al.*, 2005) have been reported after ingestion of LSD and psilocybin (e.g. Sandison *et al.*, 1954; Grof, 1975; Vollenweider *et al.*, 1997). High-amplitude bursts of lowfrequency/theta activity have also been recorded in the human hippocampus in rapid eye movement (REM) sleep (Brazier, 1968; Freemon and Walter, 1970; Giaquinto, 1973; Moiseeva and Aleksanyan, 1976; Mann *et al.*, 1997; Yu *et al.*, 1997; Bódizs *et al.*, 2001; Cantero *et al.*, 2003) and LSD given to humans immediately prior to (Toyoda, 1964; Muzio *et al.*, 1966) or during sleep (Torda, 1968) has been shown to promote REM sleep and dreaming. These studies provide converging evidence that a specific mode of cognition (primary process thinking), rests on brain states, which possess a characteristic neurophysiology.

There are also some interesting examples of medial temporal activities being influenced by psychiatric interview (Heath, 1954, 1964; Lesse *et al.*, 1955). Sporadic bursts of high-amplitude synchronous activity recorded intracranially in the medial temporal lobes (Heath, 1954, 1964; Lesse *et al.*, 1955) were detected as personal memories, with strong emotional content, were touched on. The activity desynchronized if the patient attended to his environment (Lesse *et al.*, 1955) or carried out a mathematical problem (Heath, 1954, 1964).

The abnormal limbic activity recorded in the temporal lobe aura, acute psychosis, the hallucinogenic drug state and REM sleep is often seen in the theta range (Sem-Jacobsen *et al.*, 1955; Heath *et al.*, 1955-56; Schwarz *et al.*, 1956; Sem-Jacobsen *et al.*, 1956; Monroe *et al.*, 1957; Heath and Mickle, 1960; Chapman *et al.*, 1962; Sherwood, 1962; Cantero *et al.*, 2003; Barbeau *et al.*, 2005), although bursts of high-amplitude fast activity were also seen (e.g. Lesse *et al.*, 1955; Heath *et al.*, 1955-56). Hippocampal theta in animals is reliably associated with locomotion, orienting and REM sleep (Kahana *et al.*, 2001) and also long-term potentiation (Hölscher *et al.*, 1997). Hippocampal theta depends on inputs from the septal nuclei, a major theta generator (Petsche *et al.*, 1962; Winson 1978) and another site from which the abnormal activity was recorded in non-ordinary states in humans (e.g. Heath, 1954; Sherwood, 1962). As well as providing conditions for encoding new experiences, hippocampal theta facilitates the retrieval of past experiences (Hasselmo *et al.*, 2002 Barbeau *et al.*, 2005). Scalp recordings of increased theta power associated with goal-directed cognition

(Burgess and Gruzelier, 2000; Krause *et al.*, 2000; Onton *et al.*, 2005) are unlikely to relate to the high-amplitude bursts seen in the septum and medial temporal lobes during the non-ordinary states of consciousness described above (Gevins *et al.*, 1997; Kahana *et al.*, 2001; Buzsaki 2002; Raghavachari *et al.*, 2006). The cortex is capable of generating its own theta (Silva *et al.*, 1991; Raghavachari *et al.*, 2006) and intracranial work in humans has provided more evidence for low-amplitude, *high-frequency* oscillations in the hippocampus during *attentiveness* than for theta (Heath, 1954, 1964; Lesse *et al.*, 1955; Halgren *et al.*, 1978; Arnolds *et al.*, 1980; Huh *et al.*, 1990; Meador *et al.*, 1991; Caplan *et al.*, 2001; Axmacher *et al.*, 2007). Moreover, in the non-ordinary states, activity recorded from the scalp and in the cortex is generally low-amplitude, high-frequency and desynchronous (Heath and Mickle, 1960; Chapman *et al.*, 1962; Rodin *et al.*, 1966; Cantero *et al.*, 2003); such activity is highly characteristic of REM sleep (Jouvet, 1965; Maquet *et al.*, 1996; Braun *et al.*, 1998; Cantero *et al.*, 2003; Wehrle *et al.*, 2007) and other cortical 'up' states (Steriade *et al.*, 2001) such as those induced by serotoninergic hallucinogens (Lambe and Aghajanian, 2006).

Based on empirical findings (e.g. Cañive *et al.*, 1996; Jeanmonod *et al.*, 1996, 2003; Llinás *et al.*, 1998, 1999) it has been proposed that bursts of limbic theta, recorded in the cortex as increased gamma, can index the positive symptoms of various neurological and psychiatric disorders (Llinás *et al.*, 1999; Jeanmonod *et al.*, 2003; Llinás and Steriade, 2006). Under normal conditions, cortical gamma readily suppresses low-frequency oscillations (Chen *et al.*, 2009). This function is analogous to the secondary process, but in pathological states and dreaming, limbic activity is more anarchic (e.g. Oertel *et al.*, 2007; Wehrle *et al.*, 2007) and the cortex must work harder to contain it (Llinás *et al.*, 1999; Jeanmonod *et al.*, 2003; Llinás and Steriade, 2006).

Recent intracranial EEG work in humans, using subdural electrodes recorded theta phase-modulation of high-frequency (80-150 Hz) gamma power (Canolty *et al.*, 2006). Theta modulation of gamma power was evident at rest but also during behavioural tasks. Theta-gamma coupling was highest at the trough of the theta phase. Moreover, electrodes showing the highest mean theta power also showed the strongest theta-gamma coupling. These findings imply that theta modulates coupling between theta and gamma and a number of researchers have suggested that theta may promote long-range coupling in cortical networks (e.g. von Stein and Sarnthein, 2000; Buzsaki, 2006).

Summary and synthesis

Integrating these findings, we propose that high-amplitude low-frequency (e.g. theta) discharges in limbic and paralimbic regions index the *free-energy* of the Helmholtzian scheme and mediate the *primary process* of the Freudian scheme. In waking cognition, low-frequency limbic oscillations couple to (i.e. entrain) gamma in the cortex (Canolty *et al.*, 2006; Llinás and Steriade, 2006) enabling the activity of the cortex to explain and thereby contain the activity of the limbic regions (Engel *et al.*, 2001; Friston, 2003; Chen *et al.*, 2009). In non-ordinary states, this function may be perturbed (e.g. in the case of hallucinogenic drugs, through actions at modulatory post-synaptic receptors) (Aghajanian and Marek, 1997), compromising the hierarchical organization and suppressive capacity of the intrinsic networks.

To investigate these phenomena further, neuroimaging measures of functional and effective connectivity could be employed to assess whether e.g. phasic events in REM sleep or the hallucinogenic drug state correlate with an increased limbic input to higher-level association cortices. It might transpire that in these states, limbic discharges become capable of traversing systems, which they are unable to do under normal conditions. For example, it might be possible to observe limbic discharges influencing activity in visual association areas (see Barbeau *et al.*, 2005). One might expect limbic activity to be suppressed by higher-level regions of the DMN in normal waking cognition but not in non-ordinary states. This might explain the difference between the experience of day-dreaming in the resting-state (Mason *et al.*, 2007, Q284 and Q332) and hallucinosis in non-ordinary states (Q97), where limbic activity is released from top-down control. The mechanisms of this release have been discussed previously in terms of perceptual inference and synaptic gain (Friston, 2005*b*; Stephan *et al.*, 2009), where the major determinant of synaptic gain is neuronal synchronization.

Table 2. **Some points of contact between Freud's account of the mind and empirical findings in neurobiology**

- The overlapping phenomenology of REM sleep, early and acute psychosis, the temporal lobe aura and the hallucinogenic drug state.
- All these states have been independently compared with each other previously and described independently as conducive to primary process thinking.
- The neurophysiology of these non-ordinary states is remarkably consistent both empirically and with Freud's descriptions of the 'free-flowing' energy of the primary process.
- LSD given immediately prior to or during sleep promotes REM sleep.
- The overlap between Freud's descriptions of the give-and-take relationship between ego-libido and object-libido and the give-and-take relationship between the DMN and its anti-correlated networks.
- The concordance between Freud's descriptions of the secondary process working to minimize free-energy and the free-energy account of the hierarchical organization of intrinsic networks working to minimize prediction errors.
- The integrated, compound nature of the DMN and Freud's descriptions of the integrated, compound nature of the ego.
- The development of functional connectivity between the nodes of the DMN during ontogeny, a process that parallels the emergence of ego-functions.
- Freud's account of the ego as a recipient and product of regular endogenous activity concerned with drive, memory and affect and the functional and structural connectivity of the DMN's cortical nodes with limbic structures concerned with drive, memory and affect.
- Freud's description of the ego as a tonic reservoir of activity and the high resting-state metabolism of the DMN.
- Freud's account of the ego as the seat of the sense-of-self and studies showing increased activity in the DMN during self-referential processing and a failure to deactivate the DMN in pathology characterized by withdrawal.

Discussion

In this article we have explored the notion that Freud's descriptions of the secondary process are consistent with the functional anatomy of large-scale intrinsic networks. We have proposed that intrinsic networks self-organize into hierarchical frameworks, in order to suppress the free-energy of their subordinate levels. This was associated with the function of the secondary process. We hypothesized that spontaneous fluctuations in neuronal activity in cortical nodes of the DMN function to suppress or contain otherwise anarchic and unconstrained endogenous activity in limbic and paralimbic systems, while fluctuations in subordinate networks anti-correlated with the DMN predict and counter prediction errors induced by exogenous sensory input in sensory and visceral systems.

Given the nature of this synthesis, different readers will find merit in different aspects of it. For example, some readers may see value in relating inferential coding to intrinsic networks and regard this as a potentially useful perspective on functional anatomy. Others may take the formal similarity between Freudian formulations and functionalist interpretations of neuronal processes as evidence for their construct validity. For example, the remarkable overlap between Freud's theories and modern neurobiology may engage clinicians and academics who are more familiar with (and receptive to) Freud's work (Table 2). Developing these points of contact may help anchor Freudian concepts to measurable biological phenomena and inform psychoanalytic thinking. As has been argued previously (Kandel, 1999; Solms, 2009), this process may be important for psychoanalysis. Furthermore, given the enduring, albeit marginal, influence of psychoanalysis in psychiatry, it may benefit psychiatry if psychoanalysis is properly grounded in neuroscience. This is the agenda of the Neuro-Psychoanalysis movement (www.neuro-psa.org.uk) and should assist the process of separating premises that have construct validity from those which do not.

Freud's writings contain many useful heuristics for exploring global brain function, especially in non-ordinary states of consciousness. Indeed, the Freudian model owes its origins to inferences based on unconstrained states, whereas the cognitive-behavioural approach is uncertain in this domain (Morcom and Fletcher, 2007). Science usually analyses phenomena extrospectively but in the mind-sciences especially, certain phenomena demand that we look both inwards and outwards - even if introspection entails some compromise and a confrontation with our 'it'. Freud's theories were conceived through a study of non-ordinary states, his schooling in neurology and a readiness to introspect. If they were built on false inference and loose philosophy, it is unlikely they would have endured in the way that they have. For those opposed to Freud, who would rather see his constructs dissolved into pure phenomenology and neurobiology, we put up little resistance (e.g. Q176). Phenomenology and neurobiology can stand alone. The Freudian model adds a framework for an integrated understanding of psychopathological phenomena. Once the full-character of non-ordinary states and cognition are understood, this framework may dissolve naturally.

The synthesis attempted in this article is intended to facilitate a more comprehensive understanding of psychological and neurobiological phenomena; addressing topics which have hitherto been considered incompatible with the cognitive paradigm (e.g. Morcom and Fletcher, 2007). The Freudian model should not impede hypothesis testing but rather facilitate it by emphasizing the importance of studying the phenomenology, neurophysiology and neurodynamics of different *modes* or *states* of cognition; and by indicating where we might look for anomalies. For example, altered functional connectivity between limbic and cortical nodes of the DMN may predict symptoms of ego-disturbance or primary process thinking. Identifying the neurobiological signature of ego-disturbance or primary process thinking may provide new insights into the pathogenesis of schizophrenia, given that related symptoms are prevalent in the prodromal phase (Møller and Husby, 2000; Parnas and Handset, 2003; Häfner and Maurer, 2006). Another symptom cluster, which might benefit from a Freudian treatment, is the withdrawal seen in depression and schizophrenia. The association between ego-libido and object-libido and the give-and-take between the DMN and its anti-correlated networks may be especially relevant here:

> All that we know about [libido] relates to the ego, in which at first the whole available quota of libido is stored up. We call this state absolute, primary narcissism. It lasts till the ego begins to invest the ideas of objects with libido, to transform narcissistic libido [ego-libido] into object-libido. Throughout the whole of life the ego remains the great reservoir from which libidinal investments are sent out to objects and into which they are also once more withdrawn. (Freud, 1940; Q454)

The notion of displacing energy from a default store to networks concerned with scrutinizing the external world is consistent with the functional relationship of the DMN to its anti-correlated networks, where e.g. activity is displaced from the DMN to the dorsal attention system during goal-directed cognition (Raichle *et al.*, 2001):

> We see also, broadly speaking, an antithesis between ego-libido and object-libido. The more of one is employed, the more the other becomes depleted. (Freud, 1914; Q173)

It is interesting that Freud's notion of a finite 'reservoir' of energy and the reciprocal patterns of activation between the DMN and subordinate networks both fit comfortably with hierarchical minimization of free-energy. This minimization entails recurrent message-passing between hierarchical brain systems that try to suppress the free-energy at all levels (this scheme is also called predictive coding; e.g. Jehee and Ballard, 2009). The ensuing dynamics mean that increased neuronal activity at one level suppresses neural activity encoding prediction-error in another, leading to reciprocal patterns of activation and deactivation; see Murray *et al.* (2002) for a nice empirical example of this in the visual system and Friston and Stephan (2005) for a simulation in the auditory system. In brief, the 'reservoir' of free-energy is constantly primed by surprising or unaccountable exchanges with the sensorium and is distributed throughout the hierarchy in an attempt to minimize its expression at any one level.

Recent work has shown reduced task-evoked suppressions of DMN activity in schizophrenia (Pomarol-Clotet *et al.*, 2008; Whitfield-Gabrieli *et al.*, 2009) the severity of which correlated positively with connectivity in the DMN (Whitfield-Gabrieli *et al.*, 2009). These findings support the observation that there is a reduced engagement with the external world in schizophrenia (see Table 1, row 9 and especially Q168 and Q170). In this article we have proposed that the brain's functional anatomy is organized *hierarchically* to ensure that free-energy is minimized in the most efficient way. Organized in this manner, the brain explains internal and external events and effectively discriminates between them. However, assuming that the development and maintenance of this organization is *use-dependent*, it will be jeopardized if the individual withdrawals from the external world. If the brain's hierarchical organization begins to breakdown, there may be an ensuing confusion over, among other things, what are internal and external sensations. This may be especially relevant during puberty, when the ego is forced to negotiate new demands from internal and external sources and through this, develop an adult ego. According to our model, the development of an adult ego (a properly functional DMN) is necessary to contain internal excitations and coordinate engagements with the external world. If this is not achieved, systems normally inhibited by the DMN (e.g. the salience system) may slip from its control. In the ensuing chaos, the patient may develop delusions as a compromise strategy for containing the increase in free-energy. Thus, from the free-energy perspective, withdrawal, psychomotor poverty and delusional thinking may be last resorts for someone who finds everything surprizing and unpredictable. See

Fletcher and Frith (2009) and Corlett *et al*. (2009) for a free-energy (predictive coding) treatment of false inference in schizophrenia.

As in schizophrenia, Freud recognized that a retreat from the external world is also characteristic of depression. In depression however, emphasis was laid on a loss of an intense object-love. Freud argued that the patient reacts to this loss by targeting the aggression felt towards the lost object back upon his/her own ego:

> There is no difficulty in reconstructing [the] process of [melancholia]. An object-choice, an attachment of the libido to a particular person, had at one time existed; then, owing to a real slight or disappointment coming from this loved person, the object-relationship was shattered ... But the free libido was not displaced on to another object; it was withdrawn into the ego ... Thus the shadow of the object fell upon the ego and the latter could henceforth be judged by a special agency, as though it were the forsaken object ... One or two things may be directly inferred with regards to the preconditions and effects of a process such as this. On the one hand, a strong fixation to the loved object must have been present; on the other hand, in contradiction to this, the object-[investment] must have had little power of resistance ... This contradiction seems to imply that the object-choice had been effected on a narcissistic basis, so that the object-[investment], when obstacles [came] in its way, [could] regress to narcissism. (Freud, 1917*b*, Q267)

As in schizophrenia, recent work has shown a reduced task-induced suppression of DMN activity in depression (Grimm *et al*., 2009; Sheline *et al*., 2009) and these reductions correlated positively with depression severity and ratings of hopelessness (Grimm *et al*., 2009). Reduced blood flow and activation in the dorsolateral prefrontal cortex and hyper-perfusion, metabolism and activity in limbic and medial prefrontal regions are also reliably associated with depression (e.g. Mayberg *et al*., 2005, 2007; Drevets *et al*., 2008). These findings support the notion of a withdrawal from the external world and a pathological self-focus in depression, consistent with the Freudian account (Table 1, row 9).

Conclusion

The first section of this article reviewed evidence that the development and functioning of the DMN and its functional relationship with its anti-correlated networks is consistent with that of the ego. In the second we described the phenomenology of primary process thinking, reviewed evidence that it can be observed in certain non-ordinary states and cited studies indicating that these states share a common neurophysiology. In the final section we sought to justify the synthesis and show how reference to the Freudian model might be used to understand clinically relevant phenomena in neurobiological terms.

This article does not address the efficacy of psychoanalysis as a treatment (see Fonagy, 2003 for a relevant review and Q478). Our focus is on the validity of Freudian constructs in relation to global phenomena and related theories that have recently emerged in systems neuroscience.

Finally, this synthesis was compelled by the links between psychopathology and the neurophysiology of certain non-ordinary states of consciousness, and between the functional organization of intrinsic brain networks and the secondary process as described by Freud. The synthesis is empirically-led, as are the methods we recommend for testing and applying it. The neurobiological phenomena addressed in this synthesis are central topics in contemporary neuroscience and the Freudian concepts are principal components of his model, where these components can be traced to his schooling in neurology and the influence of people like Meynert, Helmholtz, Fechner, Hering, Herbart, Charcot and Hughlings-Jackson.

Acknowledgements

We would like to thank our reviewers for very helpful guidance in presenting and extending these ideas.

Funding

KJF was funded by the Wellcome Trust. RCH is supported by the Beckley Foundation and has recently received a research grant from the Neuropsychoanalysis Association.

We express deep gratitude to both the early and contemporary pioneers of this work - the scientists, authors, practitioners, guides, research volunteers, and organizations whose work with psychedelics kept their possibilities alive - and who campaigned to revive and extend the study of psychedelics for the benefit of others. Without these pioneers, this study and the majority of research related to the transformative and therapeutic benefits of these compounds would not exist.

Thanks to funders and supporters:

Yale University Department of Psychiatry
Carey and Claudia Turnbull
Heffter Research Institute

Additional thanks:

Dr. Cyril D'Souza, MD for his role as Principal Investigator of the Yale PsilocybinDepression study.
Staff of the Schizophrenia Neuropharmacology Research Group at Yale for their dedication implementing the study.
All of the participants in our study who have entrusted us with their wellbeing.

Part 1 - Theoretical Foundation for Psilocybin-Assisted Act Therapy in Treatment of Depression

1. Introduction

1.1 Goals of This Manual

The Yale Manual for Psilocybin-Assisted Therapy of Depression provides researchers and therapists with methods, structure, and areas to consider regarding the use of psychedelic-assisted therapy in the treatment of Major Depressive Disorder (MDD). In particular, this manual illustrates a mode of utilizing Acceptance and Commitment Therapy (ACT) as a therapeutic framework for psilocybin-assisted therapy of depression.

This manual is intended for use with participants in an approved clinical trial who have provided their informed consent. In this manual, the people who participate in the experimental psychotherapy sessions are referred to as "participants" rather than as "patients" or "subjects." The manual is intended for use in conjunction with an approved study protocol, contained in a separate document, describing the study design. The design of the study for which this manual was developed involves several experimental ("dosing" or "medicine") sessions with associated preparatory and integrative therapy sessions. The number and order of sessions presented here is particular to this trial.

We consider the process of integrating the principles of ACT into psychedelic therapy to be an iterative project requiring ongoing case supervision and refinement or adaptation of the protocol. As such, the number and order of sessions may be adapted, based on the needs of other research studies. Additionally, certain aspects of the manual may be adjusted to meet the needs of different studies. However, elements of the manual designed to ensure the safety of the participant(s) or therapists should be followed. Because of the adaptable nature of the information presented in this document, the authors have adopted a mostly suggestive tone, using words like "should" or "may" in describing activities. In instances where certain practices or standards must be observed to ensure safety, the authors have chosen a directive tone, using words like, "will" or "shall."

The specific goals of this manual are to:

a. Delineate the essential elements of research-based, psychedelic-assisted therapy for individuals suffering from Major Depressive Disorder, including establishing and maintaining proper set and setting.
b. Delineate theoretical and clinical approaches drawn from Acceptance and Commitment Therapy (ACT) as a platform that offers a model for understanding and depression and treating the psychological rigidity/inflexibility that is common in MDD.
c. Provide guidelines to therapists for use of this model regarding: preparation sessions (psychoeducation), dosing (experimental) sessions, and integration (debriefing and followup) sessions.
d. Educate therapists regarding self-care practices that support this work.
e. Educate therapists regarding inclusion and exclusion criteria, screening procedures and consenting procedures.
f. Define basic criteria required to function as a study therapist.

1.2 General Elements of Psychedelic-Assisted Therapy

The term "psychedelic-assisted psychotherapy" refers to a particular mode of using psychedelic substances in which the effects of the drug, both biological and psychological, play a significant role in facilitating a psychotherapeutic intervention. This intervention begins before the first psychedelic dosing session occurs, and continues after the final dosing session. While most clinical trials using psychedelic therapy have followed the basic preparation, support, and integration model, the content of the preparation and integration sessions has varied considerably among protocols, based on the condition being treated as well as the therapeutic orientation of the researchers writing the protocol. Nonetheless, psychedelic-assisted therapies have certain common recognizable features. This therapeutic modality places significant emphasis on set, setting, preparation, integration, the creation of a supportive therapeutic container to focus and frame the effects of the psychedelic drug, and the creation and maintenance of a strong therapeutic alliance.

Traditionally, psychedelic-assisted therapy is comprised of three parts: preparation for the dosing session, support during the dosing session, and integration following it. Preparatory sessions, occurring prior to the medication session, aim to accomplish several important tasks. Therapists must develop therapeutic rapport with the participant, gather information about the participant and their history, and provide psychoeducation regarding the psychedelic experience, the therapeutic approach to be used, and expectations of the participant's active collaboration in the process. Additionally, the sessions seek to clarify the participant's expectations of the medication session. We explain the logistics of the session (how long it will last, the type of music to be utilized) and delineate acceptable boundaries of interaction between the participant and the therapist, as well as safety measures. Support in this context refers to the affirming, largely nondirective stance taken by the therapists during the experimental drug sessions. In psilocybin trials, therapists generally encourage participants to focus their mind inward during dosing sessions. Therapists provide emotional support and encourage the participant to engage with difficult thoughts, sensations, or memories that arise. They also assist the participant by meeting any immediate needs for comfort or safety. The integration phase usually begins the day after the dosing session; it involves reviewing the participant's experience during the dosing session thoroughly and, in some cases, applying therapeutic techniques to reinforce particular aspects of the experience so they foster sustained desirable patterns of thought and behavior. In other words, integration continues the therapeutic process that began during preparation sessions, and intensified during a psychedelic experience. The role of the therapist is to facilitate the integration process and help consolidate the newly developed mindset, including the actualization of insights and initiation of behavioral changes that foster recovery from depression.

It is a well-established principle that subjective effects from psilocybin administration are highly variable and are strongly influenced by psychological and environmental factors, commonly referred to as "set and setting" (Leary, Metzner, & Alpert, 1995). "Set" refers to the mindset and intention of the individual prior to the experience. This includes their beliefs, hopes, fears, traumas, personality and temperament, as well as their expectations and fantasies about psychedelic experiences and the therapists, themselves. In the context of clinical research, the participant's attitude toward the research setting, the medication, and the therapists, as well as expectations for relief also constitute important parts of the participant's set. "Setting" refers to the physical space, environment and context in which one experiences the drug effects. This includes its inhabitants (therapists or guides), as well as factors such as music, artwork, and safety equipment. The relationship with the therapists is a primary determinant of the setting. Given the influence of all these factors on the participant's experience, most research with psychedelics emphasizes the importance of set and setting to maximize safety, reduce the risk of harmful experiences, and guide therapeutic response. Guidelines for maximizing safety and minimizing risk in research studies with psychedelic substances have been published (M. Johnson, Richards, & Griffiths, 2008). Recent clinical trials with psilocybin have demonstrated that its use is remarkably safe when conducted in a safe, therapeutic environment in which individuals are adequately prepared for the experience.

1.3 Theoretical Considerations of Psilocybin-Assisted Therapy for Depression

While most clinical trials of psychedelic therapy have followed this basic model, the content of the preparation and integration sessions has varied considerably among protocols, based on the condition being treated as well as the therapeutic orientation of the researchers and therapists. Importantly, some studies have employed non-specific supportive psychotherapeutic models while others have incorporated elements of evidence-based, condition-specific therapies. An example of the latter is a study of psilocybin-assisted therapy for Alcohol Use Disorder underway at New York University School of Medicine, which integrates elements of Motivational Enhancement Therapy and Cognitive Behavioral Therapy into the familiar structure of preparation and integration sessions (Bogenschutz & Forcehimes, 2017). Numerous forms of psychosocial interventions could potentially be compatible or adaptable for use in psychedelic-assisted therapies, provided there is some theoretical synergism with the pharmacologic treatment to produce desired therapeutic outcomes.

In contrast, supportive models of psychedelic therapy are not linked to particular therapeutic orientations, nor do they target the specific disorder being treated. Instead, they provide containment, safety, and clear guidelines to help participants navigate the psychedelic experience. Some large-scale clinical trials of psilocybin treatment for major depressive disorder currently being implemented are employing nonspecific models of "psychological support" (Carhart-Harris *et al.*, 2016). While this decision is consistent with, and determined by, research priorities trials aiming to isolate drug effects from therapy effects, it also relates to the reality that it is not clear "how best to integrate the psychedelic experience into treatment models designed to have specific therapeutic effects, for example, to ameliorate the symptoms of a specific disorder" (Bogenschutz & Forcehimes, 2017).

In "psychological support only" models, the clinician is not referred to as a "therapist" but instead is named a "sitter," "guide," or "monitor." Such nonspecific models sometimes evoke the notion of an "inner healer" that abides within the psyche of the individual person and is unleashed or brought forward by the psychedelic medicine. The job of the guide, then, is to "hold space" for this natural healing process of the individual to unfold. We do not question the possibility that a self-regulating process with some potential for internally generated self-repair may be a part of psychedelic efficacy. Likewise, we also employ a nondirective approach during psilocybin dosing sessions themselves, trusting that whatever content and processes that arise will be of therapeutic value, in an analogous manner to free association in the psychoanalytic situation. However, we see numerous compelling reasons to employ a therapeutic modality with an explicit theoretical orientation in the treatment of research participants with Major Depressive Disorder.

First, we feel that an important therapeutic opportunity is lost when a condition-specific treatment modality is not employed in the overall course of psychedelic therapy for moderate to severe diagnosed mental disorders. Major Depressive Disorder is a complex, vexing, chronic condition that is best understood in neuroscientific *and* cognitive *and* behavioral *and* social dimensions. Thus, the notion that a non-specific, supportive psychosocial container is the *best* method to address such a complex clinical situation seems highly specious, and reinforces a "magic bullet" approach to psychedelic therapy, that is, one which idealizes and fetishizes the molecule itself as the active agent that is internally powerful, isolated from its social and cultural contexts. Whatever changes emerge from an intense psilocybin dosing experience will inevitably be countered by deeply ingrained patterns of thinking, feeling and behaving and are unlikely to be permanently reconfigured by even the most intense psychedelic experience. Setting the groundwork for the psychedelic experience to occur with a specific change intention, during preparatory sessions, and then reinforcing that approach during integration can help direct the psychedelic experience in ways that are known to be therapeutic for depression. As we will discuss later, this is our explicit intention in utilizing ACT as a therapeutic frame in our study. While efficacy trials of psychedelics may minimize the role of formal psychotherapy in order to separate drug effects from psychotherapy effects, we argue that the "support only" approach puts participants at risk for receiving suboptimal treatment.

Second, failure to specifically outline a coherent therapeutic approach with standardized and theorized therapy methods presents a problem for controlled research. Without a therapeutic approach being defined, much of what the sitters or guides do or say goes unaccounted for and leaves hidden the role of their therapeutic attitudes, fantasies, desires and fears. We do not believe that "psychological support" can be provided in a truly neutral manner; this ignores the existence of unconscious processes, unspoken consciously held attitudes, beliefs and emotions that live under the obfuscating blanket concept of bland and non-intrusive "support." The supportive interactions of monitors are likely to contain more than neutral space holding, especially while working with and bearing witness to the suffering of significantly depressed participants, with the therapists operating in a highly complex setting with their own deeply held relationship dynamics regarding psychedelics. In any scenario, each study therapist is likely to employ their own intuitive therapeutic modalities at different times and in different ways with different participants, even without an intention to. Thus, we believe it is more scientifically rigorous to proactively outline a therapeutic approach and structure, acknowledging there will be some reasonable variability in session content, rather than to refrain from delineating these variables at all and imagine that "non-specific support" is a specific, controlled intervention.

Third, we concur with the NIH-endorsed approach that research "interventions to change health behaviors ought to be guided by a hypothesis about why the behavior exists and how best to change it" (Nielsen *et al.*, 2018). Most psychotherapies provide answers to both of these questions. In the case of major depressive disorder, we have a panoply of theories regarding etiology and treatment, reflecting the evident truth that depression can be understood meaningfully within many different discourses (Parker, 2005). For these reasons, at the very beginning of our study, we deliberated on several empirically studied depression treatments for our therapists to employ during the course of the study.

1.4 Development of This Psychedelic-Assisted Therapy for Depression

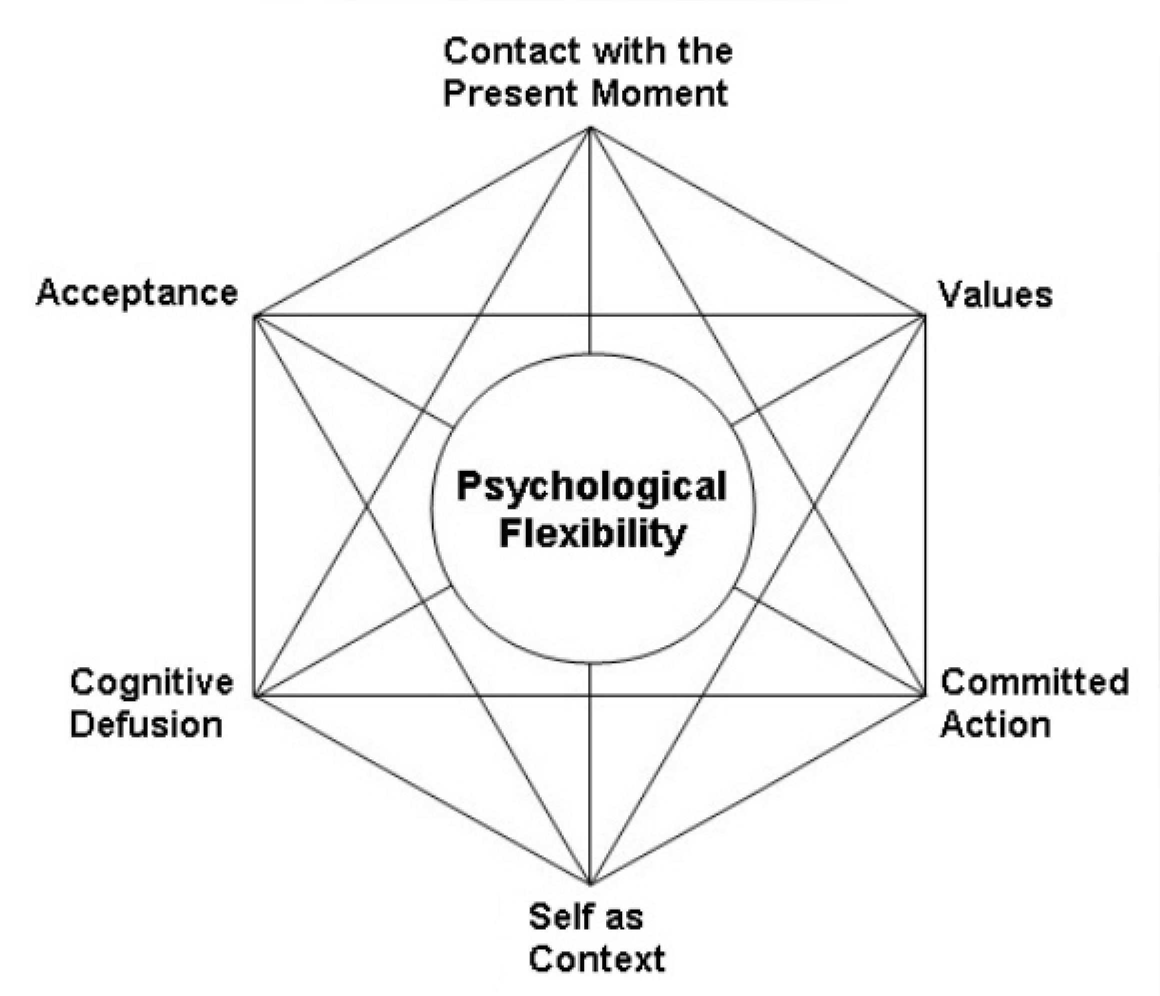
We began the process of constructing a therapy manual for psilocybin-assisted therapy of depression by studying several manualized therapies for depression that both had an evidence base and at least some conceptual overlap with psychedelic therapy. We specifically sought a therapeutic approach that would be facilitated by the effects of the psychedelic dosing sessions and also offer a structure for the preparation and integration sessions. The therapeutic modalities considered were: a) Weissman and Klerman's Interpersonal Psychotherapy (IPT) for Depression (Klerman, Weissman, Rounsaville, & Chevron, 1994); b) Frankl's Logotherapy (Schulenberg, Hutzell, Nassif, & Rogina, 2008); c) Mindfulness-Based Cognitive Therapy for Depression (Segal, Williams, & Teasdale, 2018); and d) Acceptance and Commitment Therapy (Zettle, 2007).

Our process involved outlining these key factors for each modality: the etiology of depression (how the causes of depression are understood), the therapeutic mechanism(s) (how the therapy intends to relieve depression), targeted outcomes (in addition to improvement of depressive symptoms), and the therapeutic approach (how the therapist engages with the patient). Finally, we reflected upon how the therapeutic modality may or may not relate to psychedelic experience and possible psychological mechanisms of psychedelic therapy.

Of the four modalities that were studied, two emerged as best suited for integration with psychedelic therapy in the treatment of Major Depressive Disorder: Acceptance and Commitment Therapy (ACT) and Mindfulness Based Cognitive Therapy (MBCT). Mindfulness-Based Cognitive Therapy had many positives, with a focus on non-judgmental acceptance of self, acceptance of all that arises in the mind, a focus on the present moment, and self-transcendence. All of these elements are represented in ACT, which offers, in addition, exploration of personal values (often lost in depression) and the need for values-based action (also, often missing in depression). Thus, ACT provided the most conceptual overlap with existing traditional approaches to psychedelic therapy as well as matching our intuitive notions of how psychedelic therapy may be beneficial in the treatment of depression.

1.5 Acceptance and Commitment Therapy in Psilocybin-Assisted Therapy for Major Depressive Disorder

ACT was developed through the integration of radical behaviorism and experiential/existential approaches intended to target transdiagnostic drivers of psychological distress. The FEAR acronym describes the common targets that ACT is oriented toward: "fusion, evaluation, avoidance, and reason giving" (Hayes, Strosahl, & Wilson, 2003). The common human experience of over-reliance on thoughts and beliefs over direct experiences (i.e., fusion), the evaluation of our experiences as wanted or unwanted, and attempts to avoid both external and internal (e.g. thoughts, feelings, memories) antecedents of unwanted experiences can all amplify and create the experience of suffering. Within the context of a culture that values the pursuit of positive emotions over a life lived in accordance with one's values or a sense of deeper meaning (Ryan, Huta, & Deci, 2008), attempts to control or avoid unpleasant internal states become a major source of unhappiness and psychological distress (Hayes, Strosahl, & Wilson, 2011). Though derived within the behavioral tradition, there are a number of parallels that have been noted between ACT, mindfulness interventions, and Buddhist philosophy (Hayes, 2002), including the concept of an *observer mind* or *transcendent self*, separate from the content of the mind or conceptualizations of the self, that can be experienced. In ACT, such transcendent experiences are considered to arise from amplified contact with the learned experience of the verbal relations I-you, here-there, and now-then



(McHugh, Stewart, & Almada, 2019).

The central treatment target of ACT is the development of psychological flexibility, cultivated through a careful focus on six core processes: present-moment awareness, acceptance of one's experiences, defusion from the literal belief in one's thoughts, values clarification, the identification of specific behaviors in the service of those values (committed action), and contact with a flexible experience of the self (self-as-context) (Hayes *et al.*, 2011). This "hexaflex" model is outlined in the figure below.

In contrast, psychological inflexibility can be seen as functionally related to a range of psychological problems, including depressive, anxiety, substance disorders, and eating disorders (Levin *et al.*, 2014). Within the framework of treating depression, it can be helpful to consider that experiential avoidance behaviors are better described as *experiential escape*; rather than experiencing these unwanted experiences (the internal aspects of depression, such as guilt, shame, or painful memories of loss) we see an attempt to escape painful internal experiences that are present, leading to their persistence, rather than their elimination (Zettle, 2007). A detailed description of how the processes of psychological inflexibility manifest in depression is beyond the scope of this manual. However, as a whole, this lens offers a highly valuable description of problems encountered in depressed patients in a discourse that is humanistic and of higher heuristic value than DSM-5 descriptive diagnostic criteria; it offers a construct that describes the effects of depression on thinking and behavior in ways that are amenable to specific psychological interventions. Moreover, the evidence base for ACT in the treatment of depression is growing and several studies demonstrate that it is equally effective to traditional cognitive behavioral therapies (Forman, Herbert, Moitra, Yeomans, & Geller, 2007; Zettle, 2015)

1.6 Why Utilize ACT in Psilocybin-Assisted Therapy for Major Depressive Disorder?

In this section, we will describe how we conceived of ACT principles as complementary and synergistic with those of psilocybin therapy.

First, we will discuss how ACT and our conception of psilocybin therapy share several key differences from traditional pharmacological approaches to depression (Sloshower, 2018). In the current era of biological psychiatry, mental illnesses like depression, schizophrenia, as well as addictions, are often conceptualized as brain diseases resulting from aberrant neural circuitry and chemical imbalances. To address brain-based pathology, psychiatrists primarily prescribe medications and deliver other interventions, such as electroconvulsive therapy (ECT) or transcranial magnetic stimulation (TMS), that target brain circuits, levels of neurotransmitters, and neuroreceptors. In this model, the patient is positioned as a passive recipient or consumer of such treatments, tasked only with adhering to the treatment regimen and reporting their response. Additionally, conventional pharmacological approaches to depression primarily target signs and symptoms of depression, but do not address underlying psychological, emotional, social, and spiritual causes of depressive suffering.

ACT, like most psychotherapies, differs from pharmacologic approaches in several important ways. First, it actively engages the participant in the process of recovery. For instance, in ACT, patients are required to engage in mindfulness practices, values clarification exercises, as well as behavioral activation.

Second, ACT does not explicitly set as its goal the amelioration of symptoms of depression or any other specific condition. Rather, it targets the more complex construct of psychological flexibility as discussed above. Part of increasing psychological flexibility involves acceptance of internal and external discomfort, which perhaps paradoxically for some patients, involves decreased avoidance of unpleasant thoughts and emotions, and instead, fully experiencing them with openness and acceptance. The desired outcome is to live a full, meaningful life. Doing so may indirectly lead to a reduction of depressive symptoms.

Similarly, we postulate that psilocybin-assisted therapy requires the active engagement of participants in their own healing. We question the view of psychedelic therapy as a "magic bullet" intervention, requiring only the safely contained dosing of the medicine by the suffering participant, with the magical appearance of an "inner healer" to do the necessary repair work. Certainly, psychedelic substances may have beneficial pharmacological effects that are independent of set and setting or therapeutic approach. Recent studies suggest that psychedelics can alter functional connectivity in a manner that disrupts stable spatiotemporal patterns of brain activity and increases communication between brain regions that are usually isolated (Carhart-Harris *et al.*, 2014; 2012; 2017). Our research study, which includes the ACT protocol described here[1], actively investigated the hypothesis that psilocybin induces a transient neuroplastic brain state (Ly *et al.*, 2018). While these pharmacological effects may inherently confer some degree of symptom relief or benefit, we suggest that the full potential of psychedelic therapy is more likely to be unlocked when the participant is actively engaged in a multifaceted therapeutic process of interrupting deep-seated pathological patterns of thought and behavior via integrated neurobiological and psychosocial intervention. This biopsychosocial approach (Engel, 1980) is especially important when working with chronic depressive pathology characterized by deeply ingrained rigid self-criticism, hopelessness, experiential avoidance of pain, and abandonment of valued actions. Thus, it is our hypothesis that psilocybin-assisted therapy of depressive disorders can confer more meaningful and longer lasting benefits by thoughtfully infusing ACT principles into the course of psilocybin therapy.

[1] Please see (National Institutes of Health, 2018) for more information on clinical trial NCT03554174.

In order to achieve this, we constructed our therapy protocol according to the theory that the experience of moderate to high doses of psilocybin, with preparatory priming and psychoeducation, can provide direct experiential contact with the ACT processes known to increase psychological flexibility (McCracken & Gutiérrez-Martínez, 2011) and that these deeply felt experiences may in turn be reinforced during ACT-informed therapy sessions. The ACT model involves helping patients learn skills to: a) be in the present moment, b) develop a more flexible experience of the self (self-as-context) rather than be fused to a particular personal narrative (self-as-content), c) disengage from attempts to control thoughts and emotions and instead, observe and accept them as they are (acceptance and defusion), d) to clarify values that have been lost through depression and then, e) engage in values-based action.

The intensity of the psychedelic experience may bring the participant directly and forcefully into contact with the present moment via the highly intense thoughts, sensations, emotions, and memories that may arise. These experiences are generally perceived as occurring beyond conscious control, often as a stream or flood of consciousness.[2] Participants are encouraged to surrender to their experience during drug sessions, or to "trust, let go, and be open" (W. A. Richards, 2015). The release of tension that may be experienced when this is done can serve as a deeply felt experience of the ACT principle of acceptance. Another aspect of psychedelic experience is the alteration of self-perception towards an experience of unity, or at its extreme, ego dissolution (MacLean, Leoutsakos, Johnson, & Griffiths, 2012). This may allow the experience of self-transcendence: an experience of the self that is larger than a familiar depressive identity, and thus, not as strongly identified with depressive cognition and self-critical, pessimistic, ruminative narratives. From this spacious vantage point, the participant may have an intensely felt experience of self-as-context in which the self is perceived as distinct from the thoughts that arise in the mind. Finally, it is possible for psychedelic therapy to assist people in gaining clarity of their values and priorities in life (Swift *et al*., 2017). The experience may reveal areas of life that have been neglected, aspects of self-care that need to be addressed, or how interpersonal relationships might be improved. Thus, there are many potential areas of synergism between ACT and psychedelic experience.

[2] The organization of this emergent experience occurs at a level of consciousness that is outside awareness and is a source of many speculative discourses.

Of course, not all of these processes and experiences will occur in every psychedelic experience for every individual, and study participants with long standing depressive disorders may have particularly entrenched problems of psychological inflexibility. This suggests that ultimately, multiple psilocybin sessions may be required for the successful treatment of Major Depressive Disorder. It also speaks to the important role of preparatory and integration or follow-up psychotherapy sessions to support the effects of the psilocybin dosing sessions. Integration sessions are almost universally recommended in psychedelic therapy protocols as a means of both making sense and meaning out of the experience, and helping positive changes and insights carry forth into day-to-day life. While psychedelic integration has become a buzzword in psychedelic communities, it remains somewhat vaguely conceived, undertheorized, and, in general, longs for an operational relationship to the problem being treated. It often centers a non-specific mixture of supportive listening and encouragement to engage in introspective practices, such as journaling, meditation, and spending time in nature. In the context of our study, ACT offers a template for use in integration sessions, as well as preparatory sessions with individuals who suffer from depression, which we will outline in the following section. We believe that having such a template will allow therapists to more successfully engage with a participant's familiar depressive negativism, pessimism, self-criticism, inactivity and despair as they may arise during integration sessions that follow the psilocybin dosing day.

In summary, we propose that ACT and psilocybin therapy create a synergism as both foster the core principles of psychological flexibility. It is our hypothesis that embedding psilocybin therapy within an ACT framework may amplify the response and lengthen duration of improvement from depression by actively engaging the participant, in a specific way, in making changes to their patterns of thinking and behavior. We believe these changes are a cocreation of neurobiological effects, psychological experiences, and effects of the container (ACT, the therapists and our culture) during psilocybin sessions, followed by active reinforcement by the therapists.

Note: Much of this section was adapted from Sloshower et al. (2019).

2. Therapist Foundation

2.1 Essential Therapist Background

Therapists involved in our study were required to have:

a. An up-to-date license to practice as a psychiatrist, psychologist, master's prepared social worker, or psychiatric nurse, and
b. At least 5 years' experience treating psychiatric patients in a clinical setting.

Experience in conducting psychodynamic as well as cognitive-behavioral therapies was viewed favorably, as was experience with altered states of consciousness, including yoga, mindfulness practices, holotropic breathwork, hypnosis, flotation tank work, etc.

2.2 Therapist Training

Therapists in our research study received specialized training in treating depression with psilocybin-assisted ACT therapy. The objective of the training program was to introduce them to core principles of both psychedelic therapy and ACT, and to train them to implement our therapy protocol. The training program consisted of pre-assigned didactic videos and readings, including the study therapy manual, followed by four day-long sessions. These inperson sessions consisted of close reading and discussion of the therapy manual, didactic teaching, and role plays. Day 1 of the training focused on essential elements of psychedelic therapy. Day 2 was spent reviewing core principles and techniques of ACT and how these are used in the therapy manual. Days 3 and 4 focused on role plays and experiential exercises, including a day long intensive retreat led by a peer-reviewed ACT trainer. Role-play scenarios provided therapists an opportunity to practice using ACT interventions and supporting participants through challenging psychedelic experiences.

Training methods may be adapted to suit other research studies and may include:

- Attending supplemental trainings given by MAPS, California Institute of Integral Studies' psychedelic psychotherapy program
- Attending ACT trainings
- Consultation and supervision with ACT practitioners

3. Set and Setting

> *"...the unconscious mind is often terribly frightening; we have made much of its contents unconscious because we want nothing to do with it. It takes a strong heart, honesty, and a desire to learn and face one's problems in order to enter the dark areas of our suppressed inner self. Nothing is more helpful than the presence of a kind, loving, understanding person thoroughly familiar with the dark regions of the mind - a companion who is confident of his ability to help one navigate and resolve those regions that have been an enormous burden in the past, a person who knows the wonder of being free. The willingness to surrender to the experience and allow such resolution to proceed often results in the most valuable kind of learning about one's repressed feelings, hidden values, compulsions and aspirations, and inappropriate behavior."*
> ~ Myron Stolaroff, The Secret Chief Revealed (2004)

3.1 Set: The Inner World of The Participant

"Set" and "setting" are concepts used to describe what the participant brings to the psychedelic situation and what they find there. "Set" refers to the conscious and unconscious parts of the individual leading up to the experience. This includes their beliefs, hopes, fears, traumas, personality and temperament, as well as their expectations and fantasies about psychedelic experiences and the therapists, themselves. In the context of clinical research, the participant's attitude toward the research setting, the medication, cultural attributions to psychedelics, the relationships with the therapists, as well as expectations for relief also constitute important parts of the participant's set.

We do not know what traits will lead people to have specific kinds of experiences, but through this study, we asked: what do people who experience major depression bring to the psychedelic experience? How can an ACT-based formulation guide the therapeutic process? Does the experience of psilocybin therapy help promote psychological flexibility?

3.2 Setting: The Outer World of The Participant

"Setting" refers to the physical space, environment, and context in which one experiences the drug's effects. Setting includes elements such as music, artwork, safety equipment, hospital, city, and state, etcetera and inhabitants of the space (therapists and participant). The participant's relationship with the therapists is a primary aspect of the setting.

The current standard in clinical psychedelic research is to create a warm, inviting, and private environment where participants can feel comfortable and safe to experience the medicine's intense effect and express themselves freely. To make study rooms more comfortable, researchers often decorate with plants, fresh flowers, artwork, warm colors, and homey furnishings (see Johnson *et al*. 2008 for general guidelines).

Each therapist will bring their unique combination of training and perspectives to their encounters with the participant. This includes their identity as a therapist, personal history with depression (or not), personal experience with psychedelics (or not), and experience treating patients experiencing major depression. Therapists also carry their own experiences, transferences toward the study, feelings about their home institution, transferences between therapists, and transferences between disciplines and the psychedelic community. We encourage therapists to be mindful of how their life experiences affect their emotional presence in the clinical sessions.

While one particular psychotherapeutic school of thought does not exist for psychedelic therapists, all of the practitioners in our study had significant experience working in traditional psychiatric and psychotherapeutic contexts, and training in a blend of psychodynamic and cognitive-behavioral approaches. Most had experience with mindfulness practices, including the use of mindfulness in psychotherapy. Our approach combines each therapist's background with applied ACT/MBCT principles. In this approach, it is important that all therapists receive training in treating depression from a modified ACT and MBCT point of view. This is the primary psychological framework the therapists consciously, mindfully offer.

3.3 Preparing the Physical Setting

Establishing a safe and therapeutic physical setting and mindset for the participant requires that the therapists take an active role in creating the environment. Ensure the space is conducive to the therapeutic psilocybin experience and supports the participant's ability to engage fully in their internal experience.

If possible, choose a physical setting that is private, free from interruption, and has minimal external stimuli. Make the room comfortable and, to hide or remove anything that would impart a hospital room feeling. Our study, located at the West Haven VA hospital, utilized an office space with a couch made up like a bed, pleasing artwork, and plants (see photos). We avoided religious iconography in favor of nature imagery.

The ability to play prerecorded music through speakers as well as headphones is integral to creating the setting. The deliberate and thoughtful selection of music will affect the participant's perceptions of the setting (see the section on music below).

Although a homey feeling matters, do make the participant aware of all safety equipment in place for medical monitoring. This generally includes a blood pressure and pulse monitor and locked areas for protocol materials and records. Maintaining physical safety includes providing access to treatment for possible reactions to the medicine during or immediately after each treatment session. Most reactions can be dealt with through supportive care. However, to ensure the participant's emotional comfort and physical safety, review the use of **rescue medications** with the participant as described in Part II, Section 6.9.

Only conduct psychedelic-assisted therapy in a setting where Basic Cardiac Life Support (BCLS) is immediately available and Advanced Cardiac Life Support (ACLS) can be summoned reasonably quickly in the unlikely event of an acute medical problem.

During psychedelic-assisted sessions, therapists should ensure participant's physical safety by providing adequate cautions when patients move about the room or ambulate. This includes assisting participants getting to and from the bathroom, and helping participants to remain hydrated during the test day. The setting thus includes the presence of drinking water, electrolyte-containing beverages or juices, and small snacks.

3.4 Preparing Social Support Following Medication Sessions

Following a dosing session, discharge the participant from the treatment setting only in the company of a designated support person, such as a family member or friend who understands the research project and the participant's involvement with it. The therapists need to meet or at least speak with this individual during the preparatory period prior to dosing. The therapists should assess the suitability of the support person for these tasks, which include safely accompanying the participant home, providing a safe, non-intrusive, supportive environment, responding to participant needs, and notifying the therapists of any problematic developments that need evaluation or discussion. The support person should receive education regarding the nature of the study, common and rare side effects or after effects that might emerge and advice on how to be most helpful. The support person should also be provided with contact information for both therapists and investigators as well as any other emergency contact numbers. See **departure requirements** in Part II, Section 6.9 for more information.

3.5 Planning for the Therapeutic Use of Music

Research into the specific types and forms of music most conducive to psychedelic-assisted therapies is still in its infancy and varying styles of music have historically been used in studies employing psychedelic-assisted therapies; from western classical music to Indian ragas to rock to ambient soundscapes. The role of the music, regardless of style, is to provide guidance and emotional support for a wide range of emotions throughout the session. Other general points relating to music used in psychedelic studies include:

- The playlist is crafted in such a way as to reflect and complement the psychedelic experience.
- Participants are encouraged to utilize the music to facilitate their journey, but should have the ability to decrease the volume or turn the music off, if they desire.
- Headphones are an ideal way for the participants to listen to the music as they create an internal experience with the music. Speakers may simultaneously play the music in the study room, thereby providing a valuable point of connection between therapist and participant during the session.
- Eye masks are generally available to participants, again to facilitate inward exploration and contemplation.

The music playlist we used in our study was created specifically for a phase 1 clinical trial at Imperial College London of psilocybin treatment for depression by Mendel Kaelen, PhD. Doctor Kaelen has conducted seminal research on the use of music in psychedelic-assisted therapies (see Kaelen *et al.*, 2018). In developing this playlist, he considered more than the music, thinking also about the entire soundscape the organization of the playlist would create and the ways songs transition into each other.

In order to control variables across dosing sessions and between participants, we used the same playlist for all experimental sessions in the study. However, one could argue that listening to a novel selection of music during each session would more accurately control between dosing sessions for a given participant, as the experience of re-listening is different than hearing for the first time. Another viable and more culturally considerate approach would be to develop a standardized method for customizing the music to each participant based on their cultural background and preferences.

3.6 Relationship with Therapists as Setting: The Therapists' Commitments

The therapist's responsibility is primarily to establish a well working therapeutic alliance, to support the participant's honest expressiveness, and utilize ACT treatment principles. The therapists work to support the participant's openness, self-acceptance, willingness to take action, and increased psychological flexibility. They attempt to engage with a participant's depressive way of thinking and living and access/teach strategies for change. In helping to accomplish these goals the therapist acts as empathic listeners, trustworthy guides, facilitators of self-transcendence, and also, unavoidably, each brings their own unique way of working with patients.

Psychedelic medications can have profound emotional and physical effects. To foster a therapeutic mindset and contribute to a collaborative therapeutic rapport, the therapist and participant prepare for each experimental session through numerous specific agreements discussed prior to the session:

1. The therapists commit to providing adequate preparation time and focused attention to the treatment during preparatory, dosing, debriefing and follow-up sessions.
2. Therapists and participant agree on boundaries regarding touch. Any sexual or erotic touch is explicitly forbidden. The participant is asked to agree to refrain from self-harm, harm to others, and harm to property. Participants also must remain appropriately clothed throughout the session. The participant is asked to agree to follow the therapist's recommendations regarding safety.
3. At least one of the therapist or sitters will be present in the room at all times throughout the entire psychedelic-assisted session. Both therapist and sitter commit to remain in the room with the participant throughout the psychedelic-assisted sessions except for brief periods for restroom breaks or other such needs.
4. Along with the supervising physician, the therapists will assess the participant to determine mental status and stability to leave at the end of the dosing session.
5. The therapists commit to being available by phone or text throughout the course of the study for emergency.
6. The therapists accept the extensive time commitment that may be required (exceeding the expected length of dosing sessions) should the participant need additional support.

4. Prior to the First Session with Therapists

4.1 Screening and Consent

The study investigators and study research staff conduct the screening and consenting process. For our study, the therapists did not participate in these sessions. It is worth noting that establishing a trusting rapport with the participant begins with the first contact made; this includes all screening and consenting conversations as well as sessions with therapists. Thus, the investigators, study physicians, and research staff are part of the rapport building process.

The screening and preparatory period is the time to gather participant history and to begin establishing an effective therapeutic alliance. It provides an important opportunity for the therapists and study staff to address the participant's questions and concerns, and to prepare the participant for psychedelic-assisted sessions by familiarizing them with the logistics of the sessions and the therapeutic approach that will be used, as well as establishing a tone of gentle concern, professionalism and organization. This should be done with the intention of helping the participant feel a sense of safety and comfort in the therapeutic setting. It is also an opportunity to model attitudes that will be important during psychedelic-assisted sessions, such as unhurried pacing, open ended curiosity about the participant's present moment experience (including their somatic experiences), respect for the participant's boundaries and innate wisdom about their own healing process. In clinical research, there are quite a number of questionnaires and forms to be completed, especially during the preparation period. Study staff should strive to have the necessary forms completed while still allowing time to foster a therapeutic setting and deepen the therapeutic alliance.

4.2 Prerequisites and Contraindications

Prior to enrolling in the study, participants will be given written information about the clinical trial. Participants will be given ample time to ask questions and discuss the meaning and ramifications of informed consent with staff prior to signing the Consent Form.

4.3 Commitments from The Participant (Part of the Consenting Process)

1. The participant agrees to:
    a. Attend all preparatory therapy and follow-up sessions,
    b. Complete the evaluation instruments, and
    c. Comply with dietary and drug restrictions.
2. Participants are not required to complete the study; they may withdraw consent and leave the study at any time, except during a medicine dosing session. Follow-up assessments may be performed if a participant drops out, but has not withdrawn consent.
3. The participant will be required to agree that they will remain within the treatment area until completion of each session. This means they cannot leave until the study physician and the therapists have affirmed the participant's readiness and stability to leave. (The therapists will assess the participant for signs that the psychedelic effects of the medication have ceased. The therapists and study physician will clinically assess the participant's ability to leave safely and function without medical supervision.)
4. Participants must commit to refrain from self-harm during the study, to communicate suicidal ideation to their therapists or seek emergency room care if self-harm is imminent. If they cannot make this commitment, they will be excluded from the study and referred to active clinical assessment and treatment.
5. Participants should be aware that clinical trials of psychedelic-assisted therapy often generate attention from the media. While such communication always remains the participant's choice, we encourage the participant to complete the study before engaging in public/media discussions of their experience. We encourage each participant to discuss this decision with the therapists, in order to emotionally prepare for the experience of being interviewed by the media and its aftermath.

Part 2 - Psilocybin-assisted Therapy Manual and Description of Sessions

5. Introduction

Part II outlines the content and goals of each participant encounter as designed for this particular clinical trial. In constructing our therapy protocol, we maintained the familiar structure of preparation, support, and integration sessions used in other psychedelic therapy protocols. However, we infused the sessions with ACT perspectives, principles, and interventions in various ways. Practitioners who use this manual to guide other research or clinical practice may find adding sessions or renaming sessions makes sense.

The overall goal of combining psilocybin-assisted therapy for depression with ACT is to provide a therapeutic framework that will enable participants to alter patterns of cognition and behavior that characterize depression, while increasing values-based active engagement in the world. Fostering these two types of change (which characterize psychological flexibility) through the interactive effects of the therapy and the medication sessions is the central hypothesized mechanism for change and improvement from depressive symptoms. In this manual, this approach is implemented through ACT-based Clinical Formulation and ACT-based Clinician Intervention during the psychoeducation, experimental, and debriefing/follow up sessions.

5.1 ACT-Based Clinical Formulation

While depressive and psychedelic narratives can be understood through a variety of different discourses, in our protocol, ACT provides a primary mode of understanding the nature of depressive thoughts, feelings, and behaviors, as well as participants' responses to psychedelic experiences. During preparatory sessions, therapists are instructed to listen to participants' histories of depression through an ACT lens, noticing examples of cognitive fusion, experiential avoidance, loss of values or other examples of psychological inflexibility. In this way, they begin to understand the participant's narrative along these ACT dimensions and identify which ACT processes on the hexaflex model are sites of potential exploration and change for the individual. The participant also completes the Valued Living Questionnaire (Wilson, Sandoz, Kitchens, & Roberts, 2017) at baseline, which is reviewed by the therapist for later discussion. During dosing and debriefing sessions, therapists pay attention to instances when the participant's experience either moved them toward or away from psychological flexibility. Cases of the former can serve as deeply felt reference points for more flexible and "workable" ways of thinking and behaving, which can guide the therapeutic approach during the integration period. Conversely, instances in which the participant avoided experiences of the present moment, or specific emotional states or self-concepts, can point to these particular areas that might benefit from increased attention during follow-up sessions. Thus, ACT-based clinical formulation occurs throughout all therapeutic encounters with the participant, guiding therapeutic approach and assessment of progress in an iterative manner.

5.2 ACT-Based Clinician Intervention

Holding an ACT formulation of the participant's difficulties and values in mind, therapists can provide feedback and use other interventions to target particular areas of the ACT hexaflex that need more attention, such as values-based goal setting, defusion from unworkable negative thought constructs, and overcoming experiential avoidance. For example, several of our participants expressed deeply held negative beliefs regarding their self-worth. In this case, the therapist may examine the ways that the participant is conflating a depressive thought with an absolute truth (fusion) and the resulting impacts on their behavior. During debriefing and follow-up sessions, therapists may evoke moments from the psilocybin sessions to reinforce lived experiences of increased psychological flexibility. For example, the therapist might say, "Remember how you told me you were calmly watching a stream of shapes, colors, and images move through your mind for several minutes during your dosing session? That is the kind of mindful attention we hope to cultivate through everyday mindfulness practices."

One participant in our study presented with an obsessive tendency to try to articulate perfectly during social interactions; this often resulted in anxious avoidance and social isolation. During their dosing session, however, they became very playful with their language and body movements. The therapist reminded them of this openness and freedom from fear with the hope of decreasing their experiential avoidance of future social interactions. The important part was not "making the participant wrong" for having a fixed belief about themself, but rather reinforcing their direct experience of playfulness and ease of expression.

Didactic Explanations

At several points in the protocol, the therapist directly teaches the participant about ACT principles, including during:

- Preparatory sessions, to prime the subject to register elements of the psilocybin sessions as reflecting ACT-defined shifts in thinking, behavior, and awareness of values; and
- Follow-up sessions, to help the participant solidify their understanding and implementation of ACT principles in their ongoing work toward psychological flexibility (after conclusion of their time in the research study.)

Experiential Exercises

While didactic explanations of ACT principles provide a cognitive understanding of problematic patterns and potential remedies, it is also critical that participants experience psychological flexibility on a deeper level to connect their experience with the concepts. We hypothesize that the psilocybin experience can provide this to a significant degree, especially with priming. However, we also implement ACT consistent metaphors, mindfulness practices, and worksheets to deepen this experience. We use metaphors to help convey the concepts of fusion and self-as-context. We use worksheets to help participants clarify their values, as well as the "ACT Matrix" (Polk & Schoendorff, 2014) to help participants discover how their internal experiences impact their ability to engage in values driven actions. For the purposes of standardization in research, we selected a handful of metaphors, worksheets, and exercises to include in our protocol; however, these could be flexibly employed by ACT trained clinicians in other contexts. (Table 1 outlines the sequence of therapy sessions in our treatment protocol and some of the specific ways to employ ACT in each session.)

Table 1: Overview of Therapy Session Sequence + Ways to Employ ACT in Each Session

Session Name	**Session Overview and Ways ACT is Employed**
Preparatory Psychoeducation Session #1 (2 hours)	Therapist aims to establish therapeutic alliance through: • Listening to participant's narrative of depression and treatment history to understand patterns of psychological inflexibility that are most prominent; • Psychoeducation regarding the psilocybin experience, therapeutic boundaries (e.g., touch) and safety measures; • Teaching grounding techniques including diaphragmatic breathing; • Assisting the participant in setting an intention for medication session #1.
Medication Session #1 (at 1 week)	• In line with supportive stance during medication sessions, the therapist does not provide significant ACT interventions or feedback. • ACT-based clinical formulation continues as therapist listens to emergent narratives and notes instances of psychological flexibility and inflexibility, especially present moment awareness, self-as-context, and experiential avoidance.
Debriefing Session #1 (1-2 hours, day after medication session)	• Therapist elicits complete narrative of participant's experience during medication session. • Identify and explore aspects of the participant's narrative that engage with ACT principles, as well as instances when they moved toward or away from psychological flexibility.

Debriefing Session #2 (1-2 hours, 1 week after medication session)	Therapist and participant continue to review and reflect on the participant's: • Psilocybin experience, including any emotional, mental, or lifestyle changes that followed the dosing session. • Values, by discussing the participant's completed Valued Living Questionnaire, and relative importance of valued domains of living. • Experiences living in accordance with or not living in alignment with their values.
Preparatory Psychoeducation Session #2 (2 hours, at 4 weeks)	• Conduct psychoeducation regarding: - The cognitive processes and behaviors that contribute to depression from an ACT perspective (i.e. cognitive fusion, experiential avoidance, reason-giving etc.); - How depressive patterns can be changed through an interactive process between the principles of ACT and the experience with psilocybin; and - Mindfulness practice • Through this process, the therapist aims to induce "creative hopelessness." • Assisting the participant in setting an intention for medication session #2.
Medication Session #2 (at 5 weeks)	Same as medication session #1
Debriefing Session #3 (1-2 hours, day after medication session)	Therapist elicits complete narrative of participant's experience during medication session, exploring: • Aspects of the experience in relation to ACT principles discussed previously. • Metaphors derived from psilocybin experience or from ACT (i.e. house and furniture metaphor) to aid in understanding of the principles, such as self-as-context.
Debriefing Session #4 (1-2 hours, 1 week after medication session)	Using the ACT Matrix if helpful, therapist and participant continue to review and reflect on the participant's medication experience and changes that have taken place, to explore: • What the participant values most; • How to put their values into action. Therapist may shift towards a more directive behavioral approach to help the participant to define precise actions they can take to start living in accordance with their values.
Follow-up Sessions #1 and #2 (2 and 4 weeks after medication session #2)	Therapist continues to explore and reinforce; • Insights gained from the psilocybin experience while assessing for changes in psychological flexibility; • How the dosing and therapy sessions brought each ACT process to light, using the ACT hexaflex; • Relevant ACT concepts • Successful behavioral changes and committed actions taken; • Mindfulness practices and other concrete ways the study experience can be translated into lasting changes. Therapist leads termination discussions and plans for post-study follow up care for the participant.

6. Psychoeducation Session #1

When people see some things as beautiful,
other things become ugly.
When people see some things as good,
other things become bad.

Being and non-being create each other.
Difficult and easy support each other.
Long and short define each other.
High and low depend on each other.
Before and after follow each other.
~ Lao Tzu, Tao Te Ching

By this point, the participant has completed the screening and consenting stages and is meeting their primary psychedelic therapist(s) for the first time. The tasks described in this section need to be accomplished during the first Psychoeducation Session, which lasts about two hours, or during the preparatory period leading up to the first dosing session. Due to practical and logistical study design reasons, during our study, we covered all of the tasks in one lengthy session. However, this content may be covered more effectively over the course of several preparatory sessions.

6.1 Internal Agenda for Therapists During Psychoeducation Session #1

Explicit education of the participant regarding the common cognitive and behavioral problems seen in depression will not occur until the Psychoeducation Session #2. However, during Psychoeducation Session #1, therapists will observe carefully which of these are most prominent for this participant, where strengths lie, and which particular psychological patterns seem most amenable to intervention. The therapists will also note where resilience and creativity may lie.

Cognitive Fusion

Does the participant experience thoughts, words, and language as if they were factually, absolutely true? The thought "I am a worthless person" may be experienced and believed as if it were true in some absolute sense. "I am so depressed that I cannot move" is experienced as truth when it is actually a metaphor for the experience of depression. "My life is worthless" or "I cannot do anything right" are taken at face value, rather than as thoughts that come and go and are not accurate representations of a permanent reality. "I am a depressive" or other thoughts indicating that depression comprises their core identity are examples of cognitive fusion. This intense vulnerability to internally generated pain (my thoughts are hurtful to me, I am my thoughts, I am what I think and feel), once experienced as painfully true, may then result in experiential avoidance.

Experiential Avoidance

This refers to attempts to avoid or change thoughts, feelings, memories, physical sensations and other internal experiences through:

> **Thought suppression**: trying not to think painful thoughts, suppression, distraction
>
> **Rumination**: obsessing over events, memories, narratives in a stereotyped, repetitive way that solves nothing but serves to preoccupy the mind, or
>
> **Behavioral avoidance**: social withdrawal, not taking action that might trigger depressed feelings or thoughts.

Experiential avoidance is maintained through negative reinforcement: it relieves pain in the short run but is associated with persistence or even worsening depression in the long run. For instance, "If I don't get off the couch and go to that party, I won't feel like a loser when no one wants to dance with me" leads to temporarily reduced discomfort from staying in a safe place, but more long-term depressogenic isolation and impaired social functioning.

Reason-Giving/Rumination: Searching for reasons that one experiences depression does not change the condition. In fact, searching for reasons can lead to persistence or exacerbation of the condition. This is especially true with historical events that "caused" the depression. Since no one can change the past, identifying an event that caused the depression can lead to the conclusion that recovery from depression is hopeless. For example: "My childhood trauma caused this depression, and nothing can change what happened then. Therefore, my situation is hopeless." Exploring such reasons, as if that exploration might ameliorate symptoms, is contraindicated in this approach.

Our protocol involves focusing on the relationship between the symptom and its current contextual implication.

Self-Discrepancy: Failing to live up to one's own (high) expectations and feeling like a failure generates depression. When applied to the outside world, this is useful (the house is messy, I'd prefer it neat; I will clean and vacuum and achieve that goal). This is not useful with internal assessments such as, "I am depressed because I am a terrible person, therefore I must become a good person." Internal assessments that reflect unrealistic, grandiose, or even modest self-expectations typically generate depressive cognition when not met.

Willingness vs. Desire: A common promise in psychopharmacologic treatment is that the medication treatment will *make* the individual *want* to do things, have desire, and be happier through correcting a chemical imbalance. This implies that passivity, patience and surrender to the treatment are the primary role expectations for the participant/patient. The willingness to take action to change one's life is explicitly evoked in ACT (commitment), and the passive wish to feel better solely through the medication's action is confronted as a untenable proposition. While this step (confrontation) is not addressed in Psychoeducation Session 1, the therapists take care to observe the balance of activity and passivity in the participant's narrative and behavior in session.

6.2 Building Rapport and Therapeutic Alliance

The therapist's manner of welcoming a new patient into treatment, introducing themself, and cordially beginning the process of building rapport will inform this part of the therapeutic process. The therapist may ask the participant about their experiences during the screening and consenting process, or invite the participant to ask about the experience of coming to the sessions. Including only experienced clinicians in the study will enable the principal investigator and study physician to trust the therapists to find the most effective way to make each participant comfortable and welcome.

Specific approaches include:

- Asking about the participant's experience in the research so far,
- Active listening: asking for elaboration and details to evoke specificity,
- Nodding and non-verbal sounds of understanding and empathy,
- Accepting whatever is said as the participant's lived truth,
- Empathizing with expressed affect, anxiety about being in the study, fears of failure in the study, and
- Admiring the courage and strength that allows the participant to carry on living in the face of such suffering and despair.

6.3 Review the Overall Structure of Today's Session:

Describe the things that will be covered in today's session. For example:

"First, we'd like to get to know you, your life and what things are like for you right now. We'd like to learn about your experience with depression, and what your depression treatments have been like for you. Then, we'll talk about how this psilocybin-assisted therapy treatment works and how it is different from the usual psychopharmacological treatment of depression. After that we will give you a detailed description of the psilocybin sessions. At the end, we'll give you a chance to try out the eyeshades and earphones that you'll use during the session and we'll review our schedules for all the remaining sessions that are part of the study. Sound good?"

6.4 Reviewing The Participant's Lived Experience of Depression

During the preparatory session or period, the participant is invited to describe how depression expresses itself in their life. The goal here is for the participant to speak freely, without structure from the therapist, and to feel truly heard and supported in telling their own story, however it emerges. The therapist's role is to offer empathy for the pain and suffering that the participant shares, while carrying out the *Internal Agenda* described above. The emphasis is not on accurately acquiring a psychiatric history (which has already been done) but in learning the psychological and behavioral patterns that define depression for this individual. If concerning new information emerges, for example if the participant reveals a history of self-injurious behaviors, bulimia, dissociative episodes, or similar experiences, move to a structured approach. Finding out when such experiences began, how frequently they occur(red), and the severity of the behaviors or episodes will be an appropriate intervention. Following this session, consult immediately with the principal investigator and study physician. The team may need to reconsider the person's eligibility to participate in the study.

6.5 Reviewing The Participant's Lived Experience of Psychopharmacology Treatment

Participants in this study are likely to have had several courses of treatment, experiencing numerous medications, medication combinations, possibly ECT or TMS or ketamine, and to have worked with a variety of mental health practitioners. These experiences may have left an overall transference towards treatment that is likely to be intense and unique for each person in the study. The participant may feel strongly that a psilocybin experience is their only and last hope; thus, the participant may idealize the study and feel desperate to participate. This may make it challenging for the participant to be genuine with the therapist, therefore it is valuable for therapists to explore the participant's history with psychiatric treatments in an accepting but neutral way. *Colluding with the idealization of psilocybin would be very problematic here*. However, awareness of the participant's emotional valence toward psychopharmacology as a disappointing part of their treatment history may be helpful in understanding the relationship with psilocybin and the psilocybin study.

6.6 Understand The Participant's Preconceptions About Psychedelic Experiences

Ask participants about their preconceptions, expectations, and learning history about psychedelic experiences and psilocybin. Elicit their concerns and hopes. Ask about their experiences in youth, including with marijuana, and about their conversations with friends who have had psychedelic experiences. Explore the participant's responses to Michael Pollan's book, *How To Change Your Mind* (2019) or other media representations of psilocybin therapy they have seen.

6.7 Listen for ACT "Misdemeanors" and Begin Constructing an ACT-Based Clinical Formulation

During preparatory sessions, therapists will listen to the participant through an ACT lens, noticing examples of cognitive fusion, experiential avoidance, loos of values or other examples of psychological inflexibility. In this way, they begin to understand the participant's narrative along these ACT dimensions and identify which ACT processes on the hexaflex model are sites of potential exploration and change for the individual.

6.8 Intention-Setting

> "*Having an intention is akin to having a compass aboard a sailboat. When we enter the vast ocean of expanded consciousness, there can be waves and storms, placid waters, gentle breezes, or intense winds. Having our sail raised high and compass in hand gives is a point of reference to return to, and a direction to pursue*"
> ~ Bourzat & Hunter, 2018

Intention is an important aspect of the participant's 'set' going into the experimental session. In this portion of the psychoeducation session, the therapists introduce the concept of intention setting, elicit any initial intentions, and encourage the participant to think about and solidify their intention between now and the dosing session.

Sample dialogue: "An intention is a statement of one's motivation or direction. Why are you here? What do you want for your life out of this experience? We believe that your intentions play a large part in creating your experience. We hope that the medicine and talk-therapy sessions will help you adjust the habitual thoughts and behaviors that foster your experience with depression, so you can make positive changes in your life. We do not know how the medicine session will unfold for you or just what needs to happen in the medicine session to bring about such changes. Setting your intention will help keep you on track during the dosing session, so you can get the answers and insights you need."

6.9 Educating The Participant About Psilocybin Dosing Sessions

Although some of the following will have been discussed with study staff during the consent process, it is crucial to ensure the participant understands this material. It is also valuable for this information to come from the lead study therapist. We suggest using the following scripts, or similar, when imparting this information to the participant:

a. Common Experiences with Psilocybin Script

We recommend covering the following points of psychoeducation with the participant regarding the range of experiences that may occur during a psilocybin session:

- Psilocybin is a "classical" hallucinogen that can cause profound changes in sensation, perception, thought processes, emotions, your experience of time, the nature of reality and of the self. The effects may range from very mild to very strong.
- Psilocybin alters perception. You may experience visual distortions or illusions, strong visual imagery and rarely true hallucinations. Towards the beginning of a session, you may experience cascading geometric forms and colors.
- You may see things from a radically different perspective. For instance, you may find yourself in a different reality, as if you were or are living in another time or place. You may even feel you are ceasing to exist, going crazy, or are becoming an animal, plant or other organism. Such changes may feel confusing or disturbing at times, but may also contribute to strong spiritual or mystical/transcendent experiences.
- The experience with psilocybin therapy may help you make significant positive changes in your life, but it is not a magic cure for anything. For instance, you may have psychological insights about yourself or others. These insights alone will probably not help your experience with depression unless you translate their impact and teaching into your dayto-day life and make conscious changes in the way you think and behave.
- We encourage you to take an attitude of curiosity and acceptance toward everything that happens during your session. Whatever comes up has some kind of meaning or wisdom that you can learn from, even if this meaning is not immediately obvious. It is not uncommon to feel as though your thoughts and perceptions are coming more swiftly than you can process them. We encourage you to fully allow all your emotions and perceptions, good and bad. Let memories, images, and body sensations arise. Accepting and feeling these deep and sometimes difficult emotions is the path toward being able to

change your deep-seated patterns of fear, powerlessness, guilt, and shame.

b. Difficult Experiences Script

- This medicine may cause periods of physical or emotional discomfort.
- Physically, you may experience periods of nausea, chills, anxiety, or panic. Your blood pressure may become somewhat elevated, and we will be monitoring this. Remember: although the psychological effects may feel extreme, the physiological risks of this medicine are extremely low.
- You may have bizarre sensations and experiences, and you may experience frightening images or thoughts. These may alternate rapidly. This is normal and does not mean anything is wrong. The effects will end and present no major risks to the body. It is best to embrace these experiences as they occur and seek to learn from them.
- We encourage you to "go with" or surrender to difficult experiences rather than fight them. Approach rather than flee; accept rather than reason away, lean into whatever comes up, including any impulse to run away. Strive to stay with the experience and explore it, allow yourself to be curious about what is emerging in your experience. Trust. Let go. Be open.
- What we are asking you to do is difficult, counter-intuitive and not anyone's typical pattern. It is natural to avoid negative or uncomfortable emotions and experiences. Don't be surprised if, during the session, we remind you to allow or even move toward the uncomfortable sensation or thought.
- There are methods for grounding and calming yourself, if you would like to use them. We will teach you several strategies before the end of today's session.
- If you are having difficulty of any kind, please let us know. We may be able to help you by providing reassurance, support, redirection or therapeutic touch (if you give permission for that).

c. Ski Slope Script

We have just covered a lot of information about psilocybin experiences and you may be wondering why having such an experience could be useful in treating depression. One way to think about this is that, in some ways, the mind is like a ski slope with many paths. Thoughts may start on one path, then veer in another direction. You may return to the top of the mountain and try a new thought pathway. But rumination is similar to skiing down the same path repeatedly - once you go down that one path a few times, you are more likely to go down that way again and again. Each time you do, you deepen the grooves, making it harder to turn onto a new path. In depression, people often ski down well-established ruts of thinking, feeling, and behaving. Their cognition is repetitive and inflexible.

We can think of psilocybin treatment as providing a fresh coating of snow on the mountain. With fresh powder, you have much more freedom to ski anywhere (a greater ability to think freely and tolerate a broader range of emotions). The psilocybin therapy experience can help you find new, different paths down the mountain, finding new terrain and new sights (and a sense of yourself as freer).

d. Therapist Interventions & Grounding Techniques Script

During the preparatory and integration sessions, we will have a free exchange of ideas, and ample time for conversation and discussion. During the medicine session, we invite you to take an inward journey. You can work *with* this medicine to co-create your experience. We encourage you to collect experiences and save discussion about them for later review and reflection. We will be in the room, and will check in with you if you seem to be in distress. However, for the most part, we will not seek contact with you unless you reach out to us for assistance. Please feel free to let us know if you become concerned with anything you are experiencing. You may also ask for contact at any time, either verbally or by gesturing to us, and we will always be present to help you.

e. Grounding Technique Script 1: Abdominal Breathing

- If you are feeling tense, anxious or overwhelmed during the session, abdominal breathing may be helpful.
- Direct your attention to your breathing, the sound, the feeling, the bodily experience.
- Focus on moving air with your diagram rather than your chest muscles. Imagine a balloon in your stomach connected to tube passing through your chest to your mouth. Send air through the tube to inflate the balloon, then deflate the balloon.
- With each exhalation, let go and allow tension to leave your body.
- Detailed instructions:
    1. Sit or lie flat in a comfortable position.
    2. Put one hand on your belly just below your ribs and the other hand on your chest.
    3. Take a deep breath in through your nose, and let your belly push your hand out. Your chest should not move.
    4. Breathe out through pursed lips as if you were whistling. Feel the hand on your belly go in, and use it to push all the air out.
    5. Do this breath cycle 3 to 10 times. Take your time with each breath.
    6. Notice how you feel at the end of the exercise.

f. Grounding Technique Script 2: Therapeutic Touch

- It can be helpful to establish physical contact with one or both of your therapists.
- If you agree, we may offer to hold your hand, foot, or shoulder in order to make contact with you.
- Consenting process: We would like to check with you now to see what kinds of touch you are comfortable with and under which circumstances you would like us to make physical contact. We can make physical contact with you only when you request it or use a certain gesture, or we may offer this to you if it seems like you're having a difficult time. In either case, you may always change your mind and let us know you do not want to be touched at any time. You also should feel free to signal your wish to end the touch if you desire. You may also request contact with one or the other therapist, if you prefer. Do not worry about hurting anyone's feelings; please be direct in asking for what you would like.
- We will only touch you with your advance permission. Do you give us permission to make physical contact with you during the session? Are you okay with us initiating the touch or would you prefer to be touched only when you request it? You are, of course, invited to change your answer to this question at any time.
- (If participant agrees) You may request this at any time during your medication session if you think it would be helpful. Pay attention to your inner signals regarding what is right or desirable or comfortable for you. If you cannot speak and would like physical contact, raise your hand or gesture towards us to communicate this.

Note to Therapists: If participants are experiencing ongoing physical discomfort during the dosing sessions or have significant somatic symptoms during any therapy session, it may be useful to practice the following, Awareness of Body Sensation exercise. If time permits, this may be practiced with the participant during the preparatory period.

g. Grounding Technique Script 3: Awareness of Body Sensation Exercise

- When you are experiencing strong emotion that is causing you to feel you like you are falling, this mindfulness practice can help you regain a sense of balance.
- As you are lying on the couch, arrange your body in a comfortable position, turning your attention to your body at that moment. We feel emotions in our body: perhaps a heaviness in the heart when we are sad, or maybe a tightness across the jaw when we are angry. Where in your body do you feel that emotion?
- *Pause to allow experience.*
- People sometimes report feeling emotion in the gut or stomach or chest and other places as well - in the throat or behind the eyes, for example. Notice the location where sensation is most vivid for you at this

moment. Purposefully rest your attention here.
- *Pause.*
- As you attend to sensations in this part of your body, bring awareness to their specific qualities, with sincerity but without a drive for perfection. For example, you may be noticing heaviness, pressure, tension, heat or coldness, fluttering, vibration or some other sensation. Some sensations are hard to describe. That's OK - no need to put them into words. Stay with the sensation from moment to moment, as best you can.
- *Pause.*
- *This next part should be done for a minimum of 10 minutes, up to 20 minutes, repeating the instructions periodically. Cue participant to attend to or refocus on their sensation(s) every 1 - 2 minutes, more frequently in the beginning and gradually reducing frequency and using fewer and fewer words, interrupting their process as little as possible.*
- When you notice your attention has wandered, gently return it to the sensations in your body. This is especially important if you notice yourself lost in thinking about the events or circumstances connected to the emotion.
- *Pause.*
- *Wait at least five minutes before giving the following instruction:*
- Notice if the sensations shift. They may grow weaker or stronger, or shift in location. Sensations may spread out, or shrink, or change in some other way. Whatever happens, continue resting your attention on the sensations, moment after moment after moment.
- Now, we have come to the end of the practice. As you feel ready, let your attention expand to include a sense of your body as a whole, the sounds in the room, and anything else that is here right now.

This can be followed by a brief inquiry into the experience of the participant, focused breath work, or some other grounding practice. You may also choose to ask participants about their experience of this practice during the debriefing session.

h. Rescue Medications

Review with the participant the rescue medications that will be available during the session and the indications for their use. These medications and their indications will have been discussed once during the consent process.

1. Emphasize that use of rescue medication will generally be a last resort, and that other strategies, such as relaxation exercises, will be tried first to manage anxiety or elevated blood pressure.
2. Reiterate that these medications are available to ensure the participant's safety if needed.
3. Explain that for the most part, using any rescue medications will be a joint decision, not a unilateral decision. However, in the case of an unresolvable difference of opinion, the participant must accept the clinical judgment of the study physician and therapists.

i. Practical Guidance and Safety Instructions Script

- Think of the experimental session as a multi-day experience. Minimize stress for a few days before the session and especially the day before. Spending some time in nature can help reduce stress. We also recommend reducing time on the phone or Internet. Abstaining from heavy and spicy foods is a time-honored way to prepare for spiritual experiences. You will be in the best position to benefit from the session if you are refrain from consuming alcohol and other intoxicants for one week before the session.
- We also suggest not working the day after the session, or at least having a light schedule. It is helpful to have time to reflect on what happened during the session and you may want to take some time to recover from the intensity of the session.
- On the day of the session, please arrive well rested, although you may have some difficulty sleeping the night before and this is normal. The most important thing is to be ready to devote yourself fully to the experience of the session for the full 8 hours.
- We encourage eating a light, low fat breakfast either before your arrival or at the lab. We will have light snacks, such as granola bars and crackers, as well as water and ginger ale available to you throughout

the day if you become hungry. You will also have the opportunity to order a sandwich for lunch.
- Wear loose fitting comfortable clothes, such as sweat pants, t-shirt, yoga pants, etc. Dress in layers, as it is common to have fluctuations in feeling warm or cold during the course of the medication session. Please also bring a change of clothes just in case. We invite you to bring photos, small artwork, or any objects that you feel will be supportive of your process during your session.
- On the day of the session, arrive at 8:00 a.m. to complete final questionnaires, urine toxicology, and urine pregnancy test (if indicated).
- After you take the study medication, you are required to stay in the clinic for at least six hours and until you are deemed safe to leave by study staff. Leaving before being cleared by study staff could be dangerous. **We need a clear commitment from you that you will stay in the study facility for the full duration of the session (minimum 6 hours) until you are cleared to leave by study staff.**
- We can change the light, temperature, volume of music, and provide additional blankets. Just ask, and we will do whatever we can to make you comfortable.
- Vital signs will be checked every 30 minutes for the first 2 hours, then hourly. We may ask how you're doing during these blood pressure checks; otherwise, we will generally not intrude unless you initiate contact or appear to be in distress.
- If you feel emotional, need to laugh or cry, express yourself, or move your body, please go ahead. Emotional release is normal, expected, and welcome in the session, unless your behavior threatens your safety, or the safety of other people or the study environment. We will let you know if your behavior is causing any concern and work with you to find a safe way to express yourself.
- Nausea and stomach ache may occur. Vomiting is rare, but we will have a basin available just in case.
- After about 6-7 hours, we anticipate that the effects of the medication will have almost worn off completely. At that point, we will ask you to complete some questionnaires.
- **After the session**: After you arrive home, please take some time to write down everything significant that you can remember from the session. Some of these memories and sense impressions can fade very rapidly. Don't worry if some parts of your session are difficult to recall. We will go over your experience the next day at your debriefing session. Don't feel any obligation to be sociable the night after your session. You may prefer to keep your experience of the dosing session private, even from people who care deeply and want to hear about what happened. If you wish to talk about your experience, limit discussions to people who know what you've been doing and are close to you.

j. Departure Requirements

- The participant will arrange a companion or support person to come at the end of the dosing day and accompany them home. That person will be contacted ahead of time by study staff and invited to join the end of the preparatory session in order to assess competence and appropriateness for their role, provide psychoeducation and invite questions. If they cannot attend the session in person, they must be contacted by phone (this will be the responsibility of study staff/physician rather than the therapist). The support person will be educated regarding:
    1. Basic structure of the study
    2. Range of possible after effects:
    3. Headache, common, treated with ibuprofen. 200 mg po
    4. Infrequent: changes in mood, confusion, anxiety, insomnia.
    5. Rare effects: paranoia, panic, suicidality.
    6. Methods for reaching the therapists and/or Study Physician
- The support person will be asked to come to the study area to meet the participant and therapist team upon conclusion of the session. They will be provided an information sheet containing contact information for study staff in case any concerns arise.

The authors gratefully acknowledge the use of work by Bogenschutz & Forcehimes, (2015) in this section.

6.10 Eyeshade, Music Trial and Introduction to the Physical Space

If possible, the therapists will give the participant an opportunity to adjust and try on the eyeshades that will be used in the dosing session, as well as listening to a few minutes of the music playlist. At the same time, they will offer the participant an opportunity to recline on the sofa or armchair they will use during the medication session. (Note: if this is not done during preparation, it can be done prior to dosing during the experimental session).

6.11 Ending: Questions, Recap of Details for Arrival for Session

Offer an opportunity to ask questions, confirm details for arrival at dosing session and companion pick up.

7. Medication Sessions #1 & #2

7.1 General Guidelines and Overview for Medication Sessions

Each session will last up to eight hours. Prior to the participant's arrival, ensure the room will be fully devoted to that day's dosing session exclusively. Except in case of emergency, no other persons should enter the room. Prepare the room to create a safe, warm, private atmosphere, using the checklist below.

Two study staff will be present for the entire experimental dosing session, except for bathroom breaks. The participant's therapist will be the primary person making interventions, and a study physician will be the second sitter. There will always be a study physician available and the support of nursing and research staff is also available as needed, for instance to assist with vital signs collection and completion of scales and assessments.

The sessions begin when the participant arrives and completes the assessments scheduled for that morning. Researchers and nursing staff check blood pressure and pulse to make certain that they are in an acceptable range for proceeding with the dosing. Perform urine toxicology, and if the participant is a woman of childbearing age, conduct a pregnancy test.

Session preparation checklist (gather and prepare items the morning of the session)

- Room decor: art, plants, flowers, food etc.
- Sheets, blankets, pillow
- Water-resistant sheet below cotton sheets in case of incontinence
- Emesis basin
- Standardized music system ready with ambient speakers
- Eyeshades
- Lamps and comfortable lighting
- Art materials
- Air purifier
- Blood pressure machine or manual sphygmomanometer, as decided
- Psilocybin or placebo medication
- Rescue medications, PO and IM
- Monitor rating forms and vital sign forms as required

7.1.1 Check-In

Researchers and nursing staff greet the participant and give standard medical/psychiatric assessments:

1. Check blood pressure and pulse for appropriateness for dosing,
2. Evaluate the participant for suicidality (a therapist will conduct an emergency assessment and make a referral, if needed),

3. Conduct urine toxicology and, if appropriate, a pregnancy test, and
4. Ask the participant about any changes in their medications.

Given that a lot of information was covered during preparation, we have found it useful to briefly review the following items with participants before they ingest the medication:

1. Expectations for test day (minimum 6 hours, cannot leave the floor, will have at least one person in room with them at all times)
2. Orient to bathroom location and procedure (participant to let us know if they need to use the restroom and, will be escorted)
3. Trial of eyeshades and headphones (adjust eyeshade straps, headphone volume)
4. Food: mention snacks available, take lunch order in advance
5. Review trip instructions, such as attitude of curiosity and acceptance to whatever arises, lean into experience rather than run away, 'trust, let go, be open'
6. Review techniques for dealing with distress (focus on the breath, asking therapists for support)
    a. Reconfirm consent for supportive physical contact, as well as assuring participant they can say no to these interventions at any time without offending therapists
7. Review participant's intention(s) for the session
8. Personal items brought by the participant will be available to them through the session.
9. Vital signs will be monitored at 30-minute intervals for the first two hours, then hourly.
10. Rescue medication will be available in the nearby research lab as detailed in the study protocol. After approximately five hours, art supplies may be offered to the participant.
11. Final reminder that participant can ask therapists to help them with any needs as they arise

7.1.2 Dosing

After the supervising physician clears the participant for the dosing session, the therapists have reviewed all preparatory information, and the participant is feeling ready, the therapists will offer the participant the study medication. In line with actively engaging participants in their own recover and promoting the sense that the patient is taking this medication and embarking on the experience as a matter of their own choice, we offer the medication in a dish or vessel so that the participant can pick up the capsule and take it on their own accord (i.e. we are not directly administering the medication). The therapists will invite the participant to drink an entire cup of water to help the capsule dissolve fully in the stomach. After ingestion, the participant usually will want to speak for a few minutes prior to lying down and putting on eye shades and headphones. If the participant has not already done so by 30 minutes post-dosing, they should be encouraged to lie on the couch and begin turning their focus inward. Remind them that, if they feel comfortable to do so, putting on the eyeshades will facilitate their inward focus.

Guidelines for therapist actions/attitudes during session

Principles of non-intrusive presence

The in-session therapist will maintain an attentive but non-intrusive presence. Interactions with the participants should be supportive and non-intrusive, and therapists should not attempt any significant type of psychotherapeutic work, except in addressing extremes of emotion or behavioral disruption. There will be an opportunity for brief check-ins during vital sign monitoring. As a rule, the therapist will not engage with the subject during the session except in a supportive manner when sought by the subject or if the participant appears in significant distress.

Responding to invitations to talk

If the subject requests engagement with the therapist, the therapists shall listen and respond in a supportive manner. After a few minutes, the therapist should gently suggest the participant resume an inward-directed focus, including the optional use of headphones and eyeshades. If the participant resists the suggestion, continue to work with them in a supportive and compassionate manner until they are ready to resume an inward focus. Note such instances as they may represent experiential avoidance or other important processes to be discussed during debriefing. Note that dialogue may naturally be more substantial towards the end of the session, as the medication is wearing off. As some sessions are placebo sessions, it will be more challenging to not engage in significant conversation, but therapists should attempt to conduct all experimental sessions in a similar manner if the context is a clinical trial.

Responding to intense, painful affect states

The therapists will gently encourage the subject to "lean in" or "go towards" intense or difficult affective states, rather than try to avoid or diminish them.

Responding to agitation or restlessness

The therapist will encourage breathing exercises and grounding techniques, as described above. If these are not helpful, the participant will be invited to sit up, take off the eyeshades and make visual contact with the therapists and the room. The therapists may offer reassurance that such states are to be expected and are likely to be short lived.

Responding to requests for contact

The therapist will keep in mind the subject's stated boundaries regarding touch and as appropriate will respond to requests for physical contact.

Responding to marked agitation

If the subject displays significant or marked agitation and previously mentioned interventions fail, the therapist will consult with the physician regarding the possible administration of benzodiazepine or antipsychotic medication. Medical intervention will be utilized only when agitation is persistent, and no other means to help relieve the agitation are effective.

Responding to marked, persistent paranoid reactions

If the subject presents with significant persistent paranoia the therapists must strive to remain calm and present. The therapist should reassure the subject that they are safe and offer a reminder that they have taken a powerful medicine that is affecting their thinking. It is useful to remind the participant that their experience will end within [x] hours and symptoms they are having will likely resolve quickly.

Responding to urge to undress or move about the room

If the subject begins to undress or expresses a desire to undress, the therapist will remind them of their commitment to remain fully dressed. If necessary, this will become a firm instruction. If the subject desires to move about the room, the therapist will encourage the participant to enjoy this activity briefly, and return to sitting or lying on the couch before too long.

Therapist's role/attitude/frame-of-mind during psychedelic-assisted sessions

The therapist's calm attentive self-awareness benefit both them and the participant during the dosing sessions. An empathic presence during the session will offer the best support to the participant. In so doing, the therapist encourages the participant to stay present with their inner experience, and they create a safe environment that fosters willingness to remain open to new, challenging perceptions that may arise.

The intensity of the therapeutic experience for the participant is affected by the therapist's capacity to remain calm in the face of highly intense emotion and expressiveness. The processes of "reperceiving" and radical self-acceptance need to be modeled by the therapists in order for the participant to have the best chance of learning these skills. When needed, the therapists may offer assistance to the participant in managing difficulty or confusion, while fostering the awareness that the participant's relationship with the medicine is the primary source of healing.

The therapists hold in mind any intentions for the session that the participant has identified during preparatory sessions, while also allowing for additional, perhaps unexpected, psychic material to emerge. They also consider individual psychological factors that may impact the therapeutic relationship (transference and countertransference) and seek to offer specific interventions that will be best suited to that particular individual, at that point in time.

7.1.3 First Narrative Telling (15-60 minutes)

Toward the end of the session, the participant will be invited to talk about the experience they just had, the emotions it evoked and their in-the-moment reflection on their journey. The therapist will focus on eliciting phenomenology, rather than interpreting or guiding this report. Notes will be taken by one of the therapists, which are normally given to the participant to take home as a memory aid. It is valuable to use the principles of "active listening," namely: asking open ended questions, inquiring for details and associations, avoidance of "why" questions and supporting a free-flowing report that isn't concerned with logic, rationality or productivity. This may last between 15 minutes and an hour depending on the participant. Following this (or during it) the participant will be offered water, juice, fruit and snacks to satisfy hunger and facilitate the return to ordinary consciousness.

7.1.4 Departure

About 6-7 hours after ingestion of the study medication, the majority of psilocybin effects are likely to have abated and the participant should be capable of sitting up, ambulating, conversing, and eating. They will be asked to complete any questionnaires that are part of the study. After all assessments, narratives and eating are complete, the supervising physician, in collaboration with the therapist, will assess the participant's safety for discharge from the clinic. The time from ingestion to discharge from the treatment room will be a minimum of 6 hours. So, if ingestion occurs at 9 am, the discharge will be 3 pm or later. Assessment of readiness to leave the treatment setting entails performing a mental status exam, assessment of physical safety (vital sign stability, coordination, steadiness of gait) and inquiry into any lingering effects of the medication (visual illusions, unusual beliefs, paranoia, thought processes and content, mood and insight). If cleared for discharge, the participant will be released to their companion. The next days' debriefing session, which has already been scheduled, is confirmed. The therapist ensures both the participant and the support companion have both therapist and study staff telephone numbers.

7.2 Medication Session #2

The second experimental session occurs five weeks after this one and can be conducted according to the same guidelines as described in this section.

The authors wish to acknowledge the excellent standard of care offered by Michael Bogenschutz and Alyssa Forcehimes, and to thank them for permission to use many elements of their therapy manual for psilocybin assisted therapy of alcohol dependence (Bogenschutz and Forcehimes (2015).

8. Debriefing Sessions #1 and #2

8.1 General Guidelines for Debriefing Sessions

Each debriefing session lasts one hour. The primary goal of debriefing sessions is to offer support for the participant's reflections on the medicine session. Therapists accomplish this by asking open-ended questions about the session, intended to elicit the introspective, interpersonal, spiritual or noetic insights that occurred during the session that the participant may otherwise forget or have difficulty verbalizing. Eliciting such insights may provide important clues to changes in behavior, thought, or relationships that may be intimately related to the participant's depression. Therapists will support the participant's narrative expression of their experience, and emphasize this over making interpretive interventions.

A critical related goal for therapists during debriefing is to listen for (during debriefing #1) and explore (during debriefing #2) aspects of the participant's narrative that are consistent with core ACT principles: cognitive defusion, acceptance, transcendent self, values, and action.

Thus, the therapists' agenda during debriefing is to hold an open, affirming manner while listening to the psilocybin experience, and simultaneously contextualizing the participant's narrative through core ACT principles.

8.2 Debriefing Session #1

This session takes approximately one hour and occurs the day after the first medication session.

8.2.1 Open Narrative

The therapists should use the following script or cover the following content using their own style:

1. "Today the main goal is to talk about your medication session. We are interested in learning how the session affected you, what you experienced, and most importantly, how it has affected your thinking and ideas about your experience with depression."
2. "Can you tell us everything you remember about your session, from beginning to end? What happened? What did you see? What did you hear or feel? What happened in your body?"
3. "Did anything happen that was difficult or challenging for you? Did you experience periods of negative emotion, fear, sadness, depression, or terror? Did images emerge that were hard to bear? Have any of these persisted; have any of these gotten worse since the session?"
4. "What have you been thinking and feeling since the session? Do you notice anything different about your usual depressive thoughts, beliefs, attitudes, or emotions?"
5. "How have you been sleeping and eating since yesterday's session? What was it like coming here and seeing us (the therapist and support person) today? How did family contacts feel since yesterday's session?"
6. "How are you feeling emotionally today?"

8.2.2 Session #1 Ending

As the debriefing session comes to a close, the therapist performs a mental status exam and safety assessment to evaluate for worsening mood, passive or active suicidal ideation, paranoia or confusion, persistent hallucinations, illusions, or delusions. If acute safety concerns are identified, the therapist should notify one of the study physicians to determine a plan and assess the need for further evaluation. If no acute safety concerns are identified, the therapists close the session by confirming the next appointment, and restate their availability by phone.

8.3 Debriefing Session #2

This session takes one-to-two hours and occurs one week after medication session #1. The overall goals of the second debriefing session are similar to the first but include an exploration of the role of **personal values** in recovering from depression. This debriefing session will be divided into two sections.

In the first part of the session therapists will help the participant integrate the content and process of the medication session, and their experiences during the following week.

In the second section of Debriefing Session #2, the therapists review the participant's Valued Living Questionnaire (VLQ) and values clarification list, in order to help the participant further clarify their personal values. The therapists will use the results of the participant's previously completed VLQ (done the day before first experimental session) to conduct a sincere exploration of values lost, values forgotten, values retained, and how values have changed. This may require more active exploration on the therapist's part than has been the case, as loss of values and loss of awareness of values is a common experience in depression. Not only will values be clarified, but also past activities that have demonstrated those values will be identified and explored (preferably with humor, warmth and kindness). Please note that while we utilized the VLQ as a standardized way of exploring values in our study, numerous other ACT tools and worksheets may be utilized for this purpose. The session may conclude with a metaphor to highlight important topics if appropriate.

The therapists may use the following questions to facilitate the discussion with the participant:

Debriefing of Medicine Session Script:

- "How have you been since our last session? How is your mood, your sleep and appetite? What have you been doing?"
- "Have you noticed any changes in important relationships in your life? Work? Family life?
- Where has the medicine session of (one-two-three) weeks ago been in your thoughts and emotions? Do you think of it often? When you do, what comes to mind? Do you feel its impact still being with you or does it feel like it's faded? Do you notice any changes in how you think or how your emotions express themselves?"

Values Clarification Script

- "The day before your dosing session, you completed something called a Valued Living Questionnaire. Do you remember doing that? We'd like to take some time to discuss that with you."

The therapists bring out the Valued Living Questionnaire results and give a copy to the participant. After allowing the participant to review the results, they ask the participant to respond to their feedback, which will fall along these lines as the therapist tries to help the participant clarify:

- Which values matter most to you?
- Which values do you feel most attached to?
- Which values used to be expressed in your daily life but got lost to depression?
- Which values were imposed by others, not chosen, and need to be retired?
- Values from your childhood or early adulthood have you lost touch with?
- Which values used to be important, but now are unimportant?
- Which values have been impeded by depression?
- How has living with depression led to important values being neglected or discarded?

Having gathered the participant's feedback to the VLQ, the therapists review the experience of assessing their values with the participant.

- "As we go through this exercise, what do you feel? What memories are triggered? Are you surprised at what came up for you in the questionnaire?"
- "How did these values (family, creativity, loyalty, recognition) show up during your medicine experience? Does today's conversation make you think about how you might reconnect with these values

as you move forward? How do you see your experience with depression affecting your life in terms of these values?"

8.3.1 Session #2 Ending

a. Confirm the safety and stability of the participant.
b. The participant may leave the session on their own, provided no worsening depression symptoms have emerged. If the participant has experienced worsening symptoms of depression during the debriefing session, conduct a full mental status examination and safety assessment in conjunction with the study physician, and develop an appropriate follow-up plan.
c. Confirm scheduling for the next sessions: Psychoeducation #2, Dosing #2, Debriefing #3 and Debriefing #4

9. Psychoeducation Session #2

The second psychoeducation session takes approximately two hours and occurs four weeks after the first medication session. The purpose of this session is to introduce the participant to ACT principles: the thoughts and behaviors (cognitive processes, actions) that are problematic in depression can be changed through an interactive process that links the principles of ACT and the effects psilocybin.

9.1 Checking In

Check in with the participant about their progress since the last session as in previous sessions.

9.2 Differentiating the Traditional Psychopharmacology Model of Depression Treatment from This Psychedelic-Assisted Therapy Model

Briefly introduce the participant to the basic distinction between a traditional passive pharmacologic approach to depression treatment versus the more *active* integrated medication and psychotherapeutic approach being offered in this study. This is important as patients may not only be accustomed to the pharmacologic paradigm from prior medication trials, but also may have unrealistic beliefs that psilocybin will cure them, like a 'magic bullet.' The basic principles are as follows:

a. In traditional psychopharmacology model for depression, depression is seen as a medical illness, which exists in the brain.
b. The doctor (or other MH practitioner) diagnoses the condition, explains it as such to the patient, and prescribes medication.
c. The patient's role is to report symptoms honestly, accept the doctor's diagnosis and treatment recommendation.
d. The medicine, then, is the active agent, which works to change the brain chemistry. Hopefully, improved mood, altered thought patterns, and behavioral activation follow over the coming weeks.
e. In psilocybin-assisted therapy for depression, the participant is invited to be a more active agent in changing their patterns of thinking and behaving.
f. The experience of the medicine and the relationship with the therapists are used to facilitate these changes in thinking and behaving
g. The medicine may have a profound effect in facilitating these changes, but it will likely not accomplish them on its own, and if it does, such changes are unlikely to persist without active engagement on the participant's part.
h. The therapists seek to facilitate the active utilization of the medicine experience and the therapy in bringing about meaningful changes in the participant's way of life (not simply in reducing feelings of depression).

Another key distinction is that traditional pharmacologic approaches attempt to directly ameliorate depressive symptoms - i.e. take the pill and the symptoms will hopefully get better. However, in ACT, we are actually trying to improve **psychological flexibility**, which is the ability to be present in the moment with full awareness and openness to our experience, and to take action guided by our values. In other words, "ACT assumes that a) quality of life is primarily dependent upon mindful, values-guided action, and b) this is possible regardless of how many symptoms you have - provided you respond to your symptoms with mindfulness" (Harris, 2009).

9.3 Psychoeducation Regarding Psychological Processes in Depression

The purpose of this segment of the psychoeducation session is to induce "Creative Hopelessness," or the acceptance that the participant's normal, instinctive ways of fighting depression are, in fact, sustaining it. Here, the therapist uses didactic explanation to help the participant understand how, we believe, the ACT plus psilocybin combination therapy approach works. *In our study, therapists used the following framework to structure the discussion*:

"We are going to teach you what the field of psychology has learned about depression, namely, how the minds of people with depression commonly work. It's not about understanding WHY you're depressed, but about understanding HOW the depressed mind works and changing that. In fact, focusing on WHY leads to a continuation of depression, not an amelioration of it. This is counterintuitive, but true. As I discuss some of these points, I want you to think about the ways in which they may or may not apply to you. Some may feel more relevant to your particular experience than others. Some of what we discuss may in fact feel off-base or may challenge some of the ways you have been coping with depression for a long time."

"We hope what we're going to describe here will give you some new ways to think about depression. We anticipate that the medicine sessions will help you to feel these new ideas on a deep emotional level."

The following types of depressive thinking and behaving often accompany or exacerbate depression. Using the suggested language below, the therapist should explain the types of depressive thinking and behaving and provide some examples of each.

Cognitive Fusion

"In plain language, cognitive fusion 'means getting caught up in our thoughts and allowing them to dominate our behavior' (Harris 2009). 'In a state of cognitive fusion, we're inseparable from our thoughts: we're welded to them, bonded to them, so caught up in them that we aren't even aware that we are thinking… Defusion means separating or distancing from our thoughts, letting them come and go instead of being caught up in them.'"

The therapist gives some examples of cognitive fusion in the abstract or recounts a clinical moment from their previous sessions with the participant, sharing an example of cognitive fusion that they observed in the participant. For example, the participant may say: "I know I'm not really a worthless piece of garbage, but I FEEL like I am." This is an opportunity to a) differentiate thoughts from feelings/emotions and b) bring in the ACT concept of cognitive defusion. The therapist might inquire what it actually feels like when they think they are a piece of garbage. Is there an associated bodily sensation? What is the impact on them when they have that thought? How does this thought affect the participant's relationship with the outside world? Do not try to convince the participant that they are not a worthless piece of garbage, rather that the thought is simply one thought among many others, and that it has a particular impact on them. (This ties into the next concept of workability.) Our goal is to reduce the power of the thought to guide behavior, not remove the thought. The bottom line in this section is to introduce the idea: I am not my thoughts; thoughts arise and pass away, arise and pass away, and I can observe that happening.

Introduce the concept of **workability**: The issue is not whether thoughts are true or false, but how they get in the way living life in a full, meaningful way in accordance with abiding values.

Experiential Avoidance

Explain the concept of experiential avoidance to the participant. We suggest simply using the term "avoidance", rather than the more technical term "experiential avoidance."

"Painful thoughts and feelings are extremely uncomfortable. To escape the pain, the mind may avoid experiences in one of two ways: **internal avoidance** and **external avoidance**. Internal avoidance is characterized by avoiding painful emotions or thoughts and trying to make them go away, either by suppressing them or trying to fix them through understanding (reason giving)."

Here, the therapist offers examples of internal experiential avoidance that they've seen in the weeks of working with this participant. This invokes **creative hopelessness**, showing that the participant's attempts to alleviate their depression, although understandable, have been not only ineffective, but may actually be perpetuating it. This may not be easy for them to take in, and you may see resistance or distress as familiar strategies for blunting pain are challenged. This is where **acceptance** of emotion can be put forward as part of their healing process. Acceptance refers to opening up and making room for painful feelings, sensations, urges, and emotions, rather than struggling, resisting, or getting overwhelmed by them.

External Avoidance: The therapist explains the term 'external avoidance,' and if possible, gives examples of places where this particular participant has demonstrated external experiential avoidance. It might be valuable to explain why giving up experiential avoidance is so difficult: it works, but only in the short run. Not doing something anxiety provoking leads to a reduction in painful emotion, and then, a deeply felt reinforcement for not taking action in the world. Yet studies show that prolonged experiential avoidance is associated with persisting or even worsening depression because it reinforces isolation, passivity, withdrawal and hopelessness about the ability to change.

Reason-giving/explaining why: The therapist explains that exploring narratives about the past and what "caused" the depression are not part of this therapy. This does not mean that those narratives are false or trivial, but they are not as relevant to solving the problem of depression, even though they may have caused it. Reviewing these narratives over and over is not helpful as they can limit us from having a rich, full, meaningful life.

Willingness to act in valued directions: The therapist explains the difference between willing and wanting, and introduces the idea that how the participant feels about doing something doesn't have to determine whether they actually do it. They may not want to do something, but can still be *willing* to do it. Saying "I'm going to do it *only if I feel like it*," is very problematic, perpetuates depression, and is the opposite of willingness.

The therapist tries to help the participant recognize that while there is one voice in their head that says, "I cannot go to the gym because I am immobilized by my depression," or, "I would go to the gym BUT I feel depressed, tired etcetera," they can find another voice that says, "I can go to the gym even though I feel tired and depressed." The therapist suggests a new narrative, which might be: "I can feel depressed AND go to the gym." This is the principle of 'And not But.'

9.4 Mindfulness Metaphors and Mindfulness Practice

In order to provide participants with the experience of contacting the present moment, we encourage and teach a concentration type of mindfulness practice that seems suited to the particular participant we are working with.

To introduce the concept of mindfulness, the therapist may consider offering a metaphor if that seems helpful, such as the "Sky and the Weather Metaphor" (Harris, 2009, p. 175). Introducing the concept of The Transcendent Self/Self-As-Context may also be appropriate here.

The therapist asks about the participant's prior experience with mindfulness and meditation, learning about any existing practices they maintain or have tried in the past. We want to encourage regular practice of a mindfulness or meditation at this point, which will form one means of integration after the dosing session and after their study participation ends. If the participant already practices a form of mindfulness and wishes to continue practicing that, then the therapist should gain a better understanding of that practice and set goals for regular practice. If the participant does not yet have a mindfulness practice or wishes to learn a new one, the therapist should help them learn a new one, based on their knowledge and assessment of the participant.

Examples of mindfulness practices

a. Breath awareness practices (counting breaths, following breaths, ratio breathing)
b. Touch points: awareness of the points of your body that contact the environment or themselves
c. Sound Awareness
d. Mantra meditation

It may be helpful to guide the participant through the mindfulness practice while in the session. A sample set of breath awareness instructions are as follows:

1. Find a comfortable seated position. If on the floor, use a pillow under your buttocks. Sit in cross legged position, or, if it's comfortable, in lotus position or half lotus position. If on a chair, sit on the forward 6 inches or so of the chair with your feet flat on the floor.
2. Maintain good posture. Do not slump or make the back rigidly upright.
3. Pick a point about 4 feet ahead of you on the floor. Softly rest your gaze on this point. Keep your eyes half open and half closed. If your eyes are open fully, you will be too easily distracted; if they are closed, you will too easily go to sleep or daydream.
4. Rest your hands in your lap, one on top of the other, thumbs touching. They should just touch. If they separate you may be drifting or falling asleep. If they press together you may be thinking too hard.
5. Become aware of your breathing. Breathe through your nose if you can. For every inhalation, count silently "one," then breathe out. On your next inhalation, count, "two," and so on until "ten." Once you reach "ten," start over.
6. Now here's the challenging part. If you think of any thought at all besides the number you intend to count, start over. Do not be surprised if you cannot make it to 10 or even to 3 for quite some time.
7. When thoughts come into your mind besides the number you intend to count, observe the thought, put it aside, and return to counting.
8. It is common for the thoughts to be random: things you need to do, things you have done, lists, things from a long time ago, song lyrics, and perhaps, thoughts of things you regret. Whatever they are, observe them for a moment, put them aside and return to counting.
9. You may become aware that you are frustrated by the difficulty of the task. That is ok. Observe the frustration then put it down and return to the counting.
10. Before you start, decide how long you will sit. Do not stop before that time is up. Even if you feel that you are making no headway at all. Sit with that.
11. Set a time daily to meditate, you may light a candle or do another symbolic gesture to initiate and end the sitting. However, music should not be used as it is too easily distracting.
12. This is a practice. You should not expect that it will be easy to do this. It will take time to become better at it. It is something that you will grow into.

If it hasn't already been introduced, the therapist may also guide the participant in the Awareness of Body Sensation exercise described in Psychoeducation Session #1.

9.5 Intention-Setting

Intention is an important aspect of the participant's 'set' going into the experimental session. In this section, we review the concept of intention setting, elicit the participant's intentions for the next dosing session, reflect on how their intentions may or may not have changed from the first session, and encourage the participant to think about their intention between now and the dosing session.

9.6 Ending: Questions, Recap of Details for Arrival for Session

Offer an opportunity to ask questions, confirm details for arrival at dosing session and companion pick up.

NOTE: In this study, Medication Session #2 occurs four weeks after the 1st medication session and can be conducted according to the guidelines described in Section 7.

10. Debriefing Session #3

This being human is a guest house.
Every morning a new arrival.
A joy, a depression, a meanness,
some momentary awareness comes
as an unexpected visitor.

Welcome and entertain them all!
Even if they are a crowd of sorrows,
who violently sweep your house
empty of its furniture,
still treat each guest honorably.

He may be clearing you out
for some new delight.
The dark thought, the shame, the malice,
meet them at the door laughing and
invite them in.

Be grateful for whatever comes,
because each has been sent
as a guide from beyond.
~ Rumi

The third debriefing session is one-to-two hours long and occurs the day after the second medication session. As in other debriefing sessions, the primary goal is to support the participant in reflecting on the medicine session. In this session, the therapists also strive to help the participant begin to adopt a more flexible attitude, so they can be less defined by their depressive symptoms, whether they persist or not.

10.1 Open Narrative

The therapist may use the following script verbatim, or simply as a helpful conversation guide:

- "Today our main goal is to talk about your medication session yesterday. We are interested in talking about how the session affected you, what you learned, and most importantly, how it has affected your thinking, feeling, and experience of depression."
- "What happened? What do you remember that surprised you? What did you see? What did you hear or feel? What happened in your body?"
- "What have you been thinking and feeling since the session? What do you notice about your familiar depressive thoughts, beliefs, attitudes, emotions?"
- "What happened that was difficult or challenging for you? Did you have periods of negative emotions, fear, sadness, depression, terror? Did images emerge that were beautiful or confusing or hard to bear? Have any of these persisted; have any of these gotten worse since the session?
- "In the last Psychoeducation session, we talked about many thought patterns that happen when people are in a depressed state, and how the medicine session might change some of those. Did you learn anything about how you experience depression and what perpetuates it? And, what you can do to change it?"

- "How have you been sleeping and eating since yesterday's session? What was it like coming here and seeing us today? How did family and friends feel to you after yesterday's session?"

10.2 Metaphor

If helpful and relevant to the discussion, the therapist may share the poem by Rumi (above) to illustrate the concept of *acceptance*. The following metaphor may also be offered and discussed to help the participant understand the concept of *self-as-context*:

In the **house and furniture metaphor**, the subject is invited to explore the idea of "self-as-context," vs. "self-as-content". In other words, we encourage the participant to imagine themselves as larger, or more, than their everyday sense of who they are. The house, like their true nature, is permanent and stable; the furniture is more like their thoughts and feelings, which can come and go, and may be in a constant condition of change and flux. We encourage the participant to identify with the house, their larger Self, which we suggest is distinct from their depressive symptoms. With this concept in mind, they might be able to accept or even welcome a change in the array of furniture or guests (thoughts and feelings).

10.3 Ending

As the debriefing session comes to a close, the therapist performs a mental status exam and safety assessment to evaluate for worsening mood, passive or active suicidal ideation, paranoia or confusion, persistent hallucinations, illusions, or delusions. If acute safety concerns are identified, the therapist should notify one of the study physicians to determine a plan. This may be a phone check in, an additional visit, or an assessment in the hospital ED. If no acute safety concerns are identified, the therapists close the session by confirming the next appointment, and reconfirm their availability by phone.

11. Debriefing Session #4

The fourth debriefing session occurs one week after the second medication session and lasts between one and two hours. In it, the therapist continues to help the subject move toward integrating the medication session experience with ACT and taking the values exercise into the action phase.

11.1 Open Narrative

During the first part of this session, the therapist listens to the participant's experiences since the last session in the standard open, empathic way. However, they pay close attention to the places where the participant incorporates the new patterns of thought and behavior that have been taught and, conversely, when the participant engages in thought fusion, internal or external avoidance, reason giving, unrealistic goals, confusion of wanting and willing. The therapist will take a gently didactic approach, pointing out successful changes with praise and encouragement while tactfully correcting ways of thinking/behaving that are part of the depressive condition. The therapist may remind the participant that mindfulness is an ongoing practice.

One important therapist-orientation point to make here: the participant will likely be sharing their material in a way that would evoke an exploratory response from a therapists in a traditional psychotherapy session. In an ACT-based facilitation of psychedelic therapy, the therapists are listening for the change processes defined by ACT and mindfulness-based practice; they privilege this above the content of what is reported, which may reinforce fusion.

For example, a participant may speak in an emotional way about the death of a child, and how this is preventing them from getting out of bed, taking care of other children, and leads them to feel like a bad mother. A typical therapeutic response might be to show empathy for their suffering, to talk about the death, and in doing so, likely deepen the intensity of affect around it. An ACT response might be to listen compassionately, of course, and then use defusion to draw attention to the participant's relationship with this narrative and how it impacts their ability to engage in values-driven behaviors. The therapist might point out that the participant's mind is a relentless machine generating stories and thoughts that can limit freedom to act in the world (not workable). The therapists might clarify values that have become obscured or lost in the relentless story generation and fusion with thoughts.

11.2 Values-Into-Action

This part of the conversation takes up where Debriefing Session #2 ended. By this time, the personal values of the participant have been part of the conversation for at least 3-4 weeks, and through one medication session. That experience itself can have a helpful effect on the discovery or rediscovery of abiding personal values. The therapist and participant devote 20-30 minutes to discuss the topic of values, and any value-driven actions that are underway. The therapist may refer back to the participant's Valued Living Questionnaire or use any other ACT values clarification work sheet. They may offer to assist the participant in planning values-based actions. Some participants may find a small booklet or journal to be helpful in planning. It may also be useful to employ SMART goals (Specific, Measurable, Attainable, Relevant, and Time-Bound). For instance, rather than, "I will start doing some yoga," the therapist should encourage the participant to arrive at a concrete plan, such as, "I will take the vinyasa yoga class this coming up this Wednesday at 10:30 am at the Integral Yoga Institute on Spring Street".

It is very possible, of course, that habitual patterns and processes of psychological inflexibility, as well as strong emotional states, such as fear, doubt, anger, and/or sadness may emerge in the session, especially in response to the encouragement to take action. Thus, this session will be a good opportunity to implement and practice ACT techniques for working with these intense emotional states. The therapist in this session functions somewhat like a coach. Rather than being non-directive, the therapist gently directs the participant to be present with the emotion and to practice: bringing their attention to the present moment, defusing from thoughts, and accepting what is.

It may be helpful to take 3-minute mindfulness breaks during the session to work with activated emotion or experiential avoidance.

11.3 Ending

Confirm safety and stability of the participant. After the session, the participant may go home on their own, provided no worsening depression symptoms have emerged. (If depression symptoms have worsened, a full mental status examination and clinical interview should be done, followed by stabilization of the situation.) Confirm scheduling for the next sessions.

12. Follow-up Sessions #1, #2

Follow-up sessions #1 and #2 are designed to keep moving the patient towards psychological flexibility, with an eye towards empowering them to continue making progress after their participation in the study ends. These two sessions reinforce important concepts, encourage successful changes, and facilitate further ownership of lessons and gains drawn from the psilocybin/therapy experience. The sessions provide encouragement of continued practice of mindfulness and ACT skills. The sessions also address study termination issues.

12.1 Follow-Up Session #1

This one-hour session occurs two weeks after the 2nd medication session. If case/therapy supervision is available, the therapists should use this opportunity to discuss the case and consult with the supervisor prior to this session with the explicit goal of establishing an individualized plan for the remaining sessions.

12.1.1 Check-In

This session begins with a brief, cordial check-in and catching up.

12.1.2 Termination Discussion

The therapist speaks to the fact that the participant's time in the study is coming to an end and that there will be one more session after this. The therapist invites the participant to share their feelings, thoughts, and questions about the termination sessions, including disappointment and fears that might be emerging as termination comes closer.

12.1.3 Acceptance and Commitment

This will be the focus of the session. The therapists continue the work of integrating ACT insights and behavioral changes into everyday life. Based on clinical formulation the therapist may focus on specific ACT principles. To facilitate the discussion and review progress made thus far, the therapist may introduce the ACT hexagram and explore how the medicine session and therapy have worked on the points of the ACT hexagram. The discussion focuses on the experiences of acceptance (including mindfulness and self-transcendence) and commitment (values, willingness to act) that are emerging in the participant's life. A brief meditation or period of contemplation may be incorporated into the session.

12.1.4 Begin Reviewing After-Care Plan

Begin discussing the participant's plans for ongoing treatment and self-development endeavors beyond the study. If available, give the participant a prepared list of referrals that are suitable for after-care, taking into account their financial, geographical, and clinical needs. Some examples include psychotherapy, psychopharmacologic treatment, group or individual psychedelic integration, ketamine therapy, mindfulness-based stress reduction, meditation groups, yoga studios, and exercise programs.

The discussion regarding ongoing psychotherapy may be complicated as participants may have certain feelings about returning to their prior therapist after having undergone psilocybin treatment. Participants may inquire about continuing therapy with the study therapist and so the therapist and study investigators should develop a plan and position on this ahead of time. In most clinical studies, there is either an indefinite or time-limited prohibition against clinical work together after the study. Therapists or investigators should offer to contact the participant's prior therapist to discuss progress made in the study and how this progress can be continued.

12.2 Follow-Up Session #2

This one-hour session occurs four weeks after the 2nd medication session. After briefly checking in about any significant experiences the participant had in the weeks since last session, the therapist will devote the bulk of this session to reviewing the participant's experience in the study and termination from it. The therapists and participant will reminisce, narrate, and share observations of themselves and each other during the study period. By this time in the study, there may be much improvement to celebrate.

This unique triad will have shared a distinctive experience, nothing ever to be repeated in quite the same fashion. The three will have formed a group, a container, a type of family. The therapist may reinforce practices of mindfulness and acceptance to help the participant navigate the rather abrupt termination of their short-term therapy. They will also review and confirm plans to transition back to the treating psychiatrist and therapist. They may need to restate parameters for contact after the end of the study and discuss norms around phone calls, email, texting, etcetera. The therapists may also need to review the participants ongoing responsibility to the study for assessments.

As the therapists wrap up the last session, they may express gratitude to and receive appreciation from the participant. The therapists may wish to acknowledge the participant's hard work. If it seems appropriate, the therapists may exchange hugs with the participant. If further follow up data collection is necessary, this can be reconfirmed. Finally, therapists and study staff offer goodbyes and well wishes.

13. Limitations

While our limited experience using this treatment protocol with research participants suggests it holds promise, there are a number of important limitations to the approach outlined in this manual. First, there have not been any trials comparing our approach to psilocybin treatment with non-specific psychological support only. Thus, we cannot make any definitive claims that the integration of ACT is actually more effective. We are however in the process of collecting qualitative data and self-report measures of mindfulness, changes in values, cognitive flexibility, personality, and quality of life, which we hope will shed light on which aspects of this therapy protocol are effective or helpful to participants. Additionally, our protocol does not include the full range of possible ACT interventions. This limitation is inherent to this therapy protocol being designed for a small, placebo-controlled, within subject crossover clinical trial. For scientific reasons, we attempted to standardize the therapy protocol and provide a relatively consistent approach throughout the protocol and for each participant. For reasons related to feasibility, the number of therapy sessions was constrained; we suspect that more preparatory and follow-up sessions would be optimal. As a result of these limitations, we accept that we are providing a limited form of ACT and that there are alternative, possibly superior ways that ACT could be integrated with psychedelic therapy.

13.1 Cultural Considerations of ACT-Facilitated Psychedelic Therapy

Another important potential limitation of the approach outlined here is its untested cultural relevance and acceptability among people of color and other marginalized and oppressed groups. This issue pertains to psychedelic therapy and research in general (Michaels, Purdon, Collins, & Williams, 2018) and to aspects of ACT in particular. The behavior analytic roots of ACT do not preclude a deep understanding of cultural contexts and histories of clients belonging to oppressed or stigmatized groups (Hayes & Toarmino, 1995) and preliminary evidence suggests that ACT may be effective with different ethnic groups (Woidneck, Pratt, Gundy, Nelson, & Twohig, 2012). Nonetheless, a number of core concepts and practices in ACT need to be utilized with caution and thoughtfulness when working with oppressed and stigmatized groups.

Due to a variety of cultural factors, people of color may not seek treatment until problems are severe, and most communities of color have taboos against sharing problems outside their community (Chapman, DeLapp, & Williams, 2018). Mental health literacy and self-stigma of help-seeking may also vary among cultural groups, and some people may not consider their difficulties as signs of a mental disorder as defined by Western psychiatry and psychology (Cheng, Wang, McDermott, Kridel, & Rislin, 2018). To use ACT effectively with people of color, therapists must be aware of these factors and account for them in order to build rapport with clients. At the onset of treatment, clients of color may expect therapists to provide expert advice to help them resolve urgent problems. Therefore, a non-directive approach could be experienced as frustrating, unhelpful, and invalidating. For this reason, a clear explanation of the mechanism of treatment is essential, especially when using a modality like ACT whose therapeutic concepts may seem foreign, mysterious, or counterintuitive. For instance, the idea of "acceptance" may be misinterpreted as a need to continually accept inequitable and hurtful treatment from others, rather than noting and allowing whatever responses are experienced as a result of such treatment. Marginalized individuals must be validated in their intersectional realities before acceptance can take place. Further, among people of color, the idea of "commitment" may be experienced as an extension of racist cultural assumptions about an unwillingness to be accountable. The more neutral term, "Committed action" could be used to identify small steps the participant can take to live a fuller or more meaningful life in line with their stated values. This eliminates any implied link with a lack of commitment and retains the meaning of this mechanism within ACT. In sum, therapists should take care to use the language of ACT flexibly; the concepts can be described in a number of ways, and ACT protocols for topics such as chronic pain routinely excise the use of the word "acceptance" while retaining the principles in practice (McCracken, 2005).

Caution must also be used when introducing mindfulness exercises, such as meditation, as this may be misconstrued as engaging in a competing religious practice, resulting in ambivalence or refusal to engage in such activities. Fortunately, formal meditation is only one of many ways to establish contact with the present moment and is not a necessary component of ACT. All faiths have some type of contemplative practice, and it may be best to first gain an understanding of a participant's religious beliefs so that mindfulness exercises can be made congruent with their existing religious practices and worldview.

Finally, the ACT therapeutic frame permits participants to make contact with difficult internalized experiences, like racism. However, if this occurs prematurely or is encouraged in an inappropriate manner, they may feel alienated, invalidated, or drained, thereby decreasing therapeutic rapport and opportunities to deepen psychological flexibility. This exemplifies the importance of diversity training when doing this kind of therapeutic work. Therapists should be well-practiced and comfortable discussing issues of racism and oppression with clients, and they should have a ready response for how ACT can be useful in navigating, resisting, and healing from the effects of discrimination. For example, a therapist can highlight that a client could accept distressing emotional responses to racism and still view their life circumstances as unacceptable (Sobczak & West, 2013).

Appendix A: Therapist Self-Care

Compassion and love are necessities; they are not luxuries.
Without them we cannot survive.
- Dalai Lama

Therapists are wise to engage in regular self-care in order to avoid vicarious traumatization and compassion fatigue resulting from interacting with participants' suffering. It is important that therapists continue doing their own inner work and take time for regular debriefing conversations with their co-therapist or study team. This may include an opportunity to process their own emotional responses to participants as well as peer supervision and discussion about the optimal application of the therapeutic method in specific situations. It is also an opportunity for developing and maintaining their skills as a therapeutic team by reviewing their interactions during study sessions.

What is Compassion Fatigue?

Sabo (2006) described compassion fatigue as a severe malaise resulting from the process of giving care to patients who are experiencing any type of pain (i.e., physical, emotional, social). "Compassion fatigue refers to the strain and weariness that evolves over time from offering care to suffering people."

Therapists will spend close, attuned time with participants, being fully present as they describe their life story, concerns, anxieties, and dreams during preparatory, dosing and integration sessions. This close work, especially as a new activity added to existing clinical responsibilities, may lead to compassion fatigue. The following are some simple suggestions for self-care:

a. Listen to your body and pay attention to what it is telling you. It is the best guide to staying healthy.
b. Use your body to inform your own process; are you holding your breath, is your body tense or numb, are you cold or hot?
c. Use either diaphragmatic breathing or simple breathing that expands your ribs front to back and side to side. Do a "body scan" meditation and send breath to the areas of your body that feel tight or numb.
d. Give yourself enough time before you start a session to gather your thoughts, ground yourself, and shift roles. Take enough time to feel "inner stillness."
e. Listen to your expectations and be realistic about your goals.
f. Know who you can ask for support.
g. Take time after the session to release emotions that have come up for you in the session.
h. Have a good nutritious meal after a session and do something grounding and enjoyable.
i. Taking a bath, shower, or hot tub following a session may be relaxing and calming.
j. Consider having your own ongoing psychotherapy and/or supervision with another therapist.

Appendix B: Psilocybin

> "*When we look within ourselves with psilocybin, we discover that we do not have to look outward toward the futile promise of life that circles distant stars in order to still our cosmic loneliness. We should look within; the paths of the heart lead to nearby universes full of life and affection for humanity.*"
> ~ Terence McKenna

Psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine) is a tryptamine compound that naturally occurs in species of mushrooms (*Psilocybe* sp.), such as *P. cubensis* and *P. mexicanus*. Psilocybin was first isolated and identified from *Psilocybe mexicana* by Albert Hoffman in 1957 (Passie, Seifert, Schneider, & Emrich, 2002).Once ingested, psilocybin is converted by the liver into four metabolites, of which psilocin (4-hydroxy-*N,N*-dimethyltryptamine) is the main psychoactive compound (Passie *et al.*, 2002). For the sake of simplicity and consistency with prior studies, the term psilocybin will be used in this protocol to indicate both the ingested and active substances.

Acutely, psilocybin causes profound dose-related alterations in perceptions, emotion and thought in humans, leading to its classification as a hallucinogen or psychedelic drug (Passie *et al.*, 2002). The psychedelic effects of oral psilocybin begin about 30 minutes after ingestion, peak after another 1-2 hours, and last another 1-2 hours more (Nichols, 2004; Passie *et al.*, 2002). The oral bioavailability in humans is 50%, with about 20% variability (Hasler, Bourquin, Brenneisen, Bär, & Vollenweider, 1997; Hopf & Eckert, 1974). It can be administered intravenously with a much shorter half-life and duration of subjective effects, 20 and 15-30 minutes, respectively. Once in the bloodstream, psilocybin and its metabolites are renally cleared (Passie *et al.*, 2002).

Psilocybin acts primarily as an agonist of serotonergic receptors, particularly presynaptic 5-HT_{2A} and 5-HT_{1A} receptors (Nichols, 2004; Passie *et al.*, 2002; Vollenweider & Kometer, 2010). Activation of 5-HT_{2A} receptors is believed to be the source of hallucinogenesis, as ketanserin, a selective 5-HT_{2A} receptor antagonist, blocks the psychotomimetic effects of psilocybin (Nichols, 2004; Vollenweider, Vollenweider-Scherpenhuyzen, Bäbler, Vogel, & Hell, 1998). Other serotonergic hallucinogens, such as LSD, mescaline, and dimethyltryptamine (DMT), also directly bind 5-HT_{2A} receptors (Nichols, 2004). However, unlike LSD, psilocybin has no affinity for dopamine D2 receptors though a D2 blocker, such as haloperidol, has been shown to reduce the acute effects of psilocybin, indicating known overlap between the serotonergic and dopaminergic circuits in the brain. (Passie *et al.*, 2002; Vollenweider, Vontobel, Hell, & Leenders, 1999).

Safety of Psilocybin

Psilocybin mushrooms have been used ritually by native peoples in Mexico in religious ceremonies and for healing from as early as 3000 years ago up until the 16th century, after which the Spanish prohibited their use (Schultes, Hofmann, & Rätsch, 2001). Historical accounts of psilocybin-associated fatalities involve situations that are clearly compounded by other factors: accidental over-ingestion by a child, concomitant heroin overdose, and psychological disturbance (e.g. jumping from a window with the belief one could fly) (Nichols, 2004; van Amsterdam, Opperhuizen, & van den Brink, 2011). The effective oral hallucinogenic dose of psilocybin ranges from 4 to 20 mg (0.06 to 0.3 mg/kg), whereas the LD50 for oral psilocybin ranges from 12.5 mg/kg in rabbits to 285 mg/kg in rats and mice (Nichols, 2004; Passie *et al.*, 2002; Usdin & Efron, 1972; van Amsterdam *et al.*, 2011). Therefore, the LD50 in humans is likely on the order of grams (Passie *et al.*, 2002). There are no human cases describing birth defects or complications of pregnancy associated with the use of psilocybin. In a report of one woman who took psilocybin every two weeks during pregnancy, there were no detrimental effects to herself or her baby (Leary, Litwin, & Metzner, 1963). Furthermore, as with other hallucinogens (e.g. LSD), psilocybin is non-addicting (Nichols, 2004; van Amsterdam *et al.*, 2011).

A recent summary of 227 experimental psilocybin sessions in 110 healthy subjects demonstrated safety and tolerability of psilocybin with no evidence of increasing risk of subsequent drug abuse, persisting disorders of perception, prolonged psychosis or other longterm impairments of functioning (Studerus, Kometer, Hasler, & Vollenweider, 2011). The study reported that fatigue, headaches or head pain, lack of energy, difficulty concentrating, a "gone" feeling, lack of appetite, and heavy or tired legs were the most frequent adverse events experienced in the 24 hours following a session with oral psilocybin (Studerus *et al*., 2011). Other unpleasant somatic effects include dizziness, nausea, flushing, increased heart rate, and elevated blood pressure (M. Johnson *et al*., 2008).

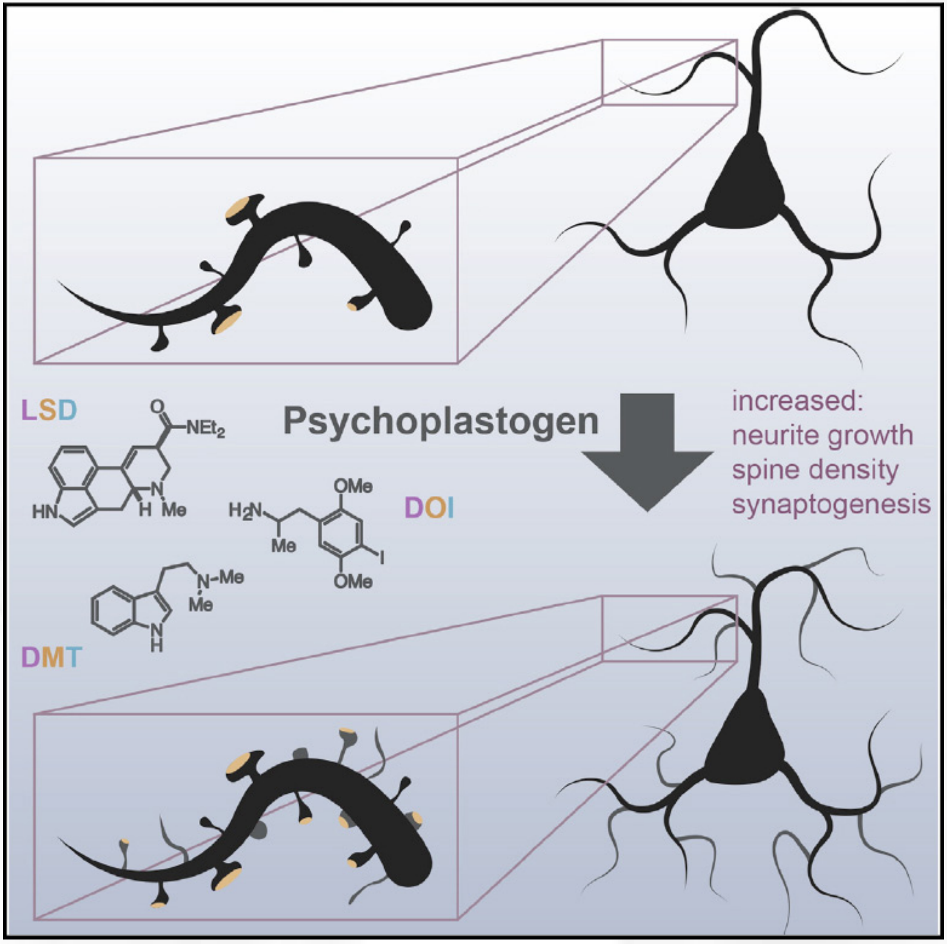
Graphical Abstract



Summary

Atrophy of neurons in the prefrontal cortex (PFC) plays a key role in the pathophysiology of depression and related disorders. The ability to promote both structural and functional plasticity in the PFC has been hypothesized to underlie the fast-acting antidepressant properties of the dissociative anesthetic ketamine. Here, we report that, like ketamine, serotonergic psychedelics are capable of robustly increasing neuritogenesis and/or spinogenesis both *in vitro* and *in vivo*. These changes in neuronal structure are accompanied by increased synapse number and function, as measured by fluorescence microscopy and electrophysiology. The structural changes induced by psychedelics appear to result from stimulation of the TrkB, mTOR, and 5-HT$_{2A}$ signaling pathways and could possibly explain the clinical effectiveness of these compounds. Our results underscore the therapeutic potential of psychedelics and, importantly, identify several lead scaffolds for medicinal chemistry efforts focused on developing plasticity-promoting compounds as safe, effective, and fast-acting treatments for depression and related disorders.

Introduction

Neuropsychiatric diseases, including mood and anxiety disorders, are some of the leading causes of disability worldwide and place an enormous economic burden on society (Gustavsson *et al.*, 2011; Whiteford *et al.*, 2013). Approximately one-third of patients will not respond to current antidepressant drugs, and those who do will usually require at least 2-4 weeks of treatment before they experience any beneficial effects (Rush *et al.*, 2006). Depression, post-traumatic stress disorder (PTSD), and addiction share common neural circuitry (Arnsten, 2009; Russo *et al.*, 2009; Peters *et al.*, 2010; Russo and Nestler, 2013) and have high comorbidity (Kelly and Daley, 2013). A preponderance of evidence from a combination of human imaging, postmortem studies, and animal models suggests that atrophy of neurons in the prefrontal cortex (PFC) plays a key role in the pathophysiology of depression and related disorders and is precipitated and/or exacerbated by stress (Arnsten, 2009; Autry and Monteggia, 2012; Christoffel *et al.*, 2011; Duman and Aghajanian, 2012; Duman *et al.*, 2016; Izquierdo *et al.*, 2006; Pittenger and Duman, 2008; Qiao *et al.*, 2016; Russo and Nestler, 2013). These structural changes, such as the retraction of neurites, loss of dendritic spines, and elimination of synapses, can potentially be counteracted by compounds capable of promoting structural and functional neural plasticity in the PFC (Castrén and Antila, 2017; Cramer *et al.*, 2011; Duman, 2002; Hayley and Litteljohn, 2013; Kolb and Muhammad, 2014; Krystal *et al.*, 2009; Mathew *et al.*, 2008), providing a general solution to treating all of these related diseases. However, only a relatively small number of compounds capable of promoting plasticity in the PFC have been identified so far, each with significant drawbacks (Castrén and Antila, 2017). Of these, the dissociative anesthetic ketamine has shown the most promise, revitalizing the field of molecular psychiatry in recent years.

Ketamine has demonstrated remarkable clinical potential as a fast-acting antidepressant (Berman *et al.*, 2000; Ionescu *et al.*, 2016; Zarate *et al.*, 2012), even exhibiting efficacy in treatment-resistant populations (Diaz-Granados *et al.*, 2010; Murrough *et al.*, 2013; Zarate *et al.*, 2006). Additionally, it has shown promise for treating PTSD (Feder *et al.*, 2014) and heroin addiction (Krupitsky *et al.*, 2002). Animal models suggest that its therapeutic effects stem from its ability to promote the growth of dendritic spines, increase the synthesis of synaptic proteins, and strengthen synaptic responses (Autry *et al.*, 2011; Browne and Lucki, 2013; Li *et al.*, 2010).

Like ketamine, serotonergic psychedelics and entactogens have demonstrated rapid and long-lasting antidepressant and anxiolytic effects in the clinic after a single dose (Bouso *et al.*, 2008; Carhart-Harris and Goodwin, 2017; Grob *et al.*, 2011; Mithoefer *et al.*, 2013, 2016; Nichols *et al.*, 2017; Sanches *et al.*, 2016; Osório *et al.*, 2015), including in treatment-resistant populations (Carhart-Harris *et al.*, 2016, 2017; Mithoefer *et al.*, 2011; Oehen *et al.*, 2013; Rucker *et al.*, 2016). In fact, there have been numerous clinical trials in the past 30 years examining the therapeutic effects of these drugs (Dos Santos *et al.*, 2016), with 3,4-methylenedioxymethamphetamine (MDMA) recently receiving the "breakthrough therapy" designation by the Food and Drug Administration for treating PTSD. Furthermore, classical psychedelics and entactogens produce antidepressant and anxiolytic responses in rodent behavioral tests, such as the forced swim test (Cameron *et al.*, 2018) and fear extinction learning (Cameron *et al.*, 2018; Catlow *et al.*, 2013; Young *et al.*, 2015), paradigms for which ketamine has also been shown to be effective (Autry *et al.*, 2011; Girgenti *et al.*, 2017; Li *et al.*, 2010). Despite the promising antidepressant, anxiolytic, and anti-addictive properties of serotonergic psychedelics, their therapeutic mechanism of action remains poorly understood, and concerns about safety have severely limited their clinical usefulness.

Because of the similarities between classical serotonergic psychedelics and ketamine in both preclinical models and clinical studies, we reasoned that their therapeutic effects might result from a shared ability to promote structural and functional neural plasticity in cortical neurons. Here, we report that serotonergic psychedelics and entactogens from a variety of chemical classes (e.g., amphetamine, tryptamine, and ergoline) display plasticity-promoting properties comparable to or greater than ketamine. Like ketamine, these compounds stimulate structural plasticity by activating the mammalian target of rapamycin (mTOR). To classify the growing number of compounds capable of rapidly promoting induced plasticity (Castrén and Antila, 2017), we introduce the term "psychoplastogen," from the Greek roots psych- (mind), -plast (molded), and -gen (producing). Our work strengthens the growing body of literature indicating that psychoplastogens capable of promoting plasticity in the PFC might have value as fast-acting antidepressants and anxiolytics with efficacy in treatment-resistant populations and suggests that it may be possible to use classical psychedelics as lead structures for identifying safer alternatives.

Results

Psychedelics Promote Neuritogenesis

Because atrophy of cortical neurons is believed to be a contributing factor to the development of mood and anxiety disorders (Christoffel *et al.*, 2011; Duman and Aghajanian, 2012), we first treated cultured cortical neurons with psychedelics from a variety of structural classes (Figures 1A and S1A) and measured the resulting changes in various morphological features. Using Sholl analysis (Ristanovi&cacute; *et al.*, 2006), we observed that several psychedelics increased dendritic arbor complexity comparably to ketamine, as measured by the area under the curve of the Sholl plots as well as the maximum number of crossings (Figures 1B-1E and S1B-S1E). This increase in arbor complexity appeared to result from large changes in both the number of dendritic branches and the total length of the arbors (Figures 1F, 1H, S1F, and S1H). Psychedelics had a limited effect on the number of primary dendrites and did not alter the length of the longest dendrite (Figures 1G, 1I, S1G, and S1I).

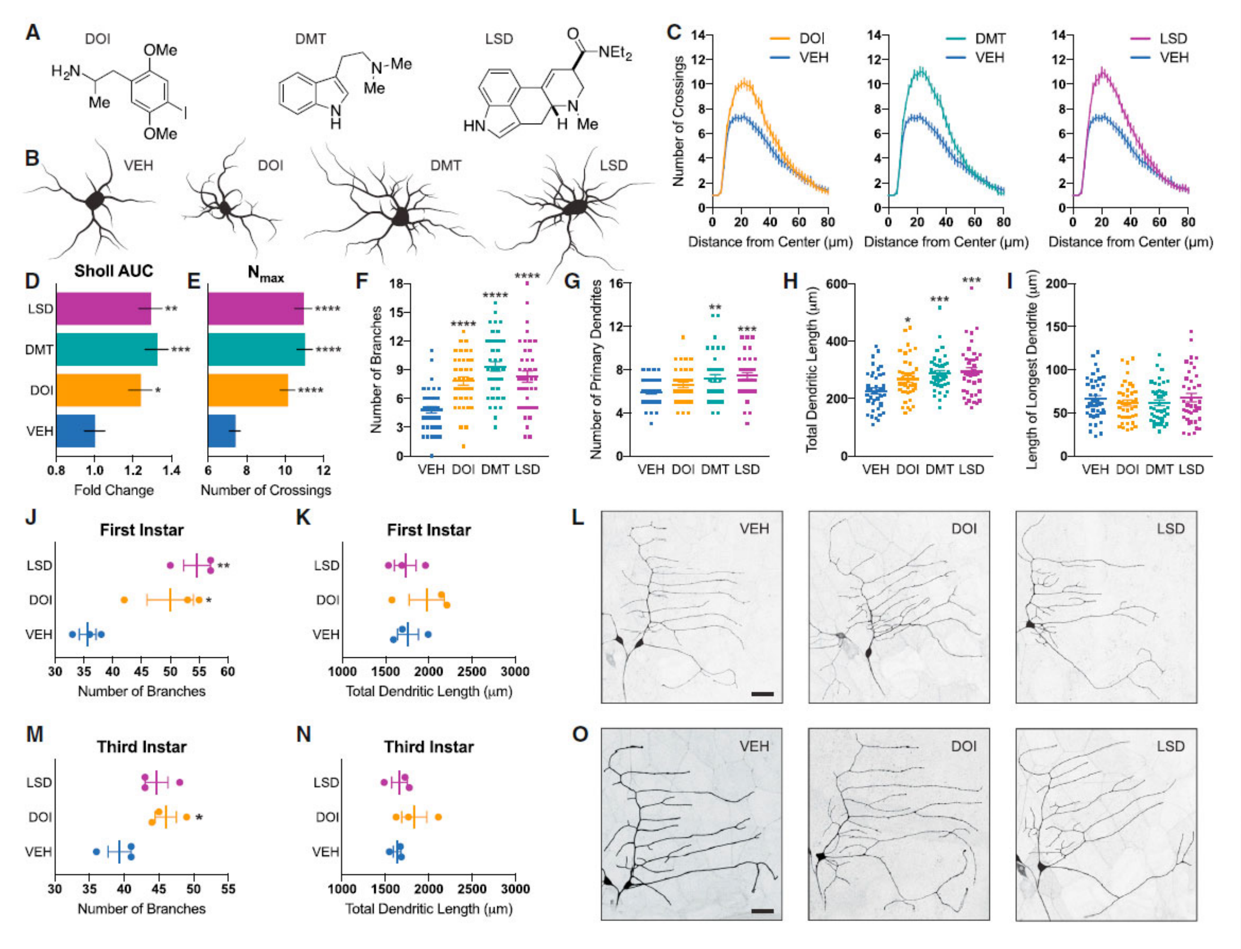


Figure 1. Psychedelics Promote Neuritogenesis both *In Vitro* and *In Vivo*
(A) Chemical structures of psychedelics.
(B) Representative tracings of cortical neurons (DIV6) treated with compounds.
(C) Sholl analysis demonstrates that psychedelics increase dendritic arbor complexity (*n* = 39-41 neurons).
(D) Area under the curve (AUC) of the Sholl plots in (C).
(E) Maximum number of crossings (N_{max}) of the Sholl plots in (C).
(F-I) Cortical neurons treated with psychedelics display an increase in the number of branches (F), the number of primary dendrites (G), and the total length of the dendritic arbor (H) but not the length of the longest dendrite (I).
(J and K) Class I neurons from *Drosophila* larvae treated with psychedelics during the first instar display increased branching (J) but not total length of the dendritic arbor (K) (*n* = 3 neurons).
(L) Representative images of neurons from (J) and (K).
(M and N) Class I neurons from *Drosophila* larvae treated with psychedelics during the third instar display increased branching (M) but not total length of the dendritic arbor (N) (*n* = 3 neurons).
(O) Representative images from (M) and (N).
$*p < 0.05$, $**p < 0.01$, $***p < 0.001$, $****p < 0.0001$, as compared to vehicle control (VEH). Scale bars, 30 µm. Data are represented as mean ± SEM. See also Figures S1-S5.

Nearly all psychedelic compounds tested were capable of robustly promoting neuritogenesis, with comparable effects being produced by tryptamines (*N,N*-dimethyltryptamine [DMT] and psilocin), amphetamines (2,5-dimethoxy-4-iodoamphetamine [DOI] and MDMA), and ergolines (lysergic acid diethylamide [LSD]). As a positive control, we treated cells with 7,8-dihydroxyflavone (DHF), a psychoplastogen structurally dissimilar to classical psychedelics (Jang *et al.*, 2010), and found that it also increased dendritic arbor complexity (Figure S2). This neurite outgrowth structural phenotype seems to only be induced by select compounds because serotonin and D-amphetamine, molecules that are chemically related to classical psychedelics and entactogens, exerted minimal to no effects on neuritogenesis (Figure S2).

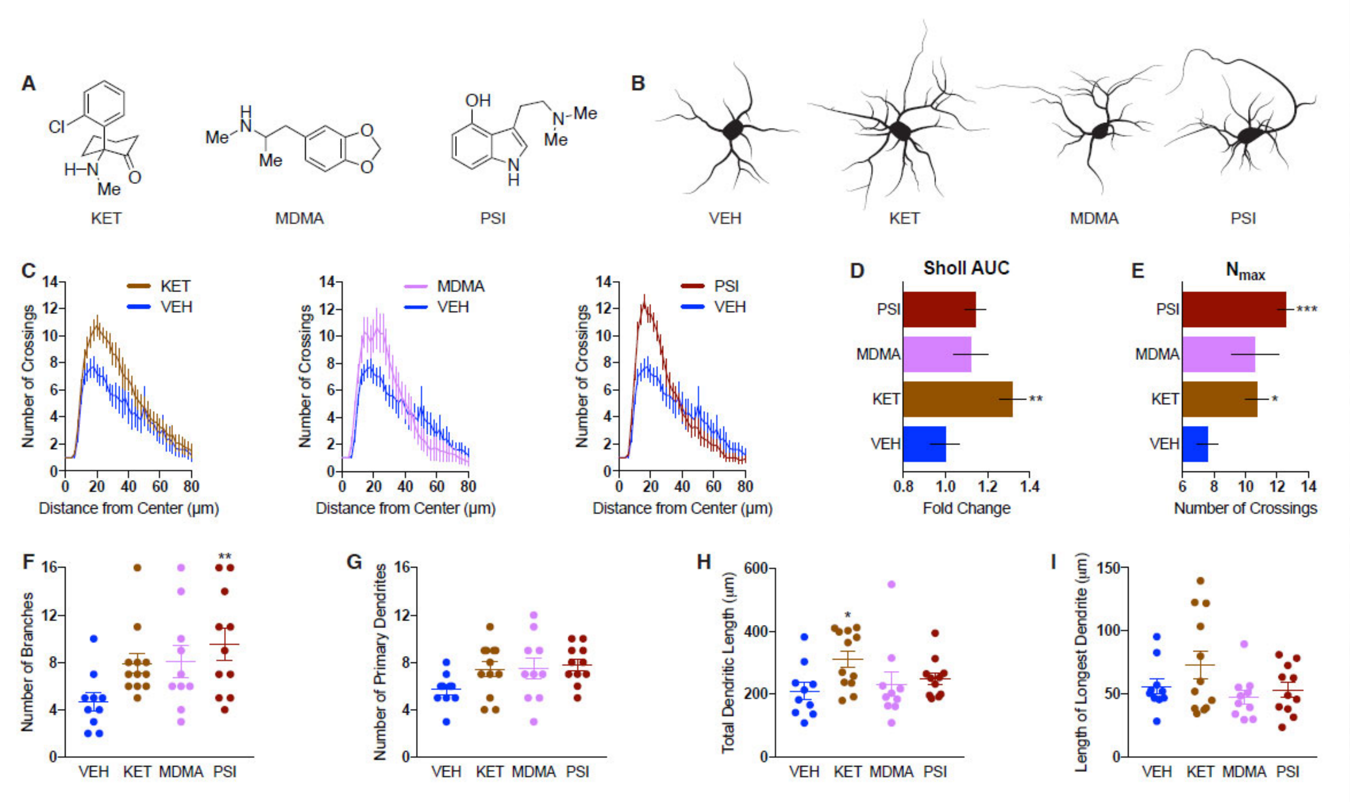

Figure S1. Psychedelics Promote Neuritogenesis (Additional Compounds), Related to Figure 1. (A) Chemical structures of additional psychedelics used in these studies. (B) Representative tracings of cultured embryonic rat cortical neurons (DIV6) treated with compounds. (C) Sholl analysis (circle radii = 2 μm increments) demonstrates that cultured cortical neurons treated with several psychedelics have more complex dendritic arbors as compared to vehicle control (n = 10-12 neurons per treatment). (D) Area under the curve (AUC) of the Sholl plots in C. (E) Maximum number of crossings (N_{max}) of the Sholl plots in C. (F-I) Cultured cortical neurons treated with several psychedelics display a trend towards an increase in the number of branch points (F), the number of primary dendrites (G), and the total length of the dendritic arbor (H), but not the length of the longest dendrite (I). Error bars represent s.e.m. $*p < 0.05$, $**p < 0.01$, $***p < 0.001$, as compared to vehicle control (One-way ANOVA with Dunnett's post-hoc test). VEH = vehicle, KET= ketamine, MDMA = (±)-3,4-methylenedioxymethamphetamine, PSI = psilocin.

To establish the relative potencies and efficacies of hallucinogens and entactogens for promoting neurite outgrowth, we conducted 8-point dose-response studies (Figure S3). We defined 100% and 0% efficacy as the maximum number of crossings induced by ketamine (10 μM) and vehicle (0.1% DMSO), respectively. We chose the 10 μM concentration of ketamine as the upper limit because this concentration of ketamine is reached in the brain following intraperitoneal administration of an antidepressant dose in rats (Yang *et al.*, 2018). For consistency, we used this same concentration when testing the effects of psychedelics and entactogens, with DMT being the only exception. We used a maximum 90 μM concentration of DMT in our studies to more closely mimic the brain concentration of DMT in rats treated with an antidepressant dose (Cohen and Vogel, 1972; Cameron *et al.*, 2018). In this neuritogenesis assay, ketamine's half maximal effective concentration (EC_{50}) value was 132 nM. Surprisingly, the majority of the psychedelics and entactogens we tested exhibited significantly greater potency than ketamine, with LSD being particularly potent (EC_{50} = 0.409 nM). In fact, LSD exhibited activity across 8 orders of magnitude into the low picomolar range (Figure S3).

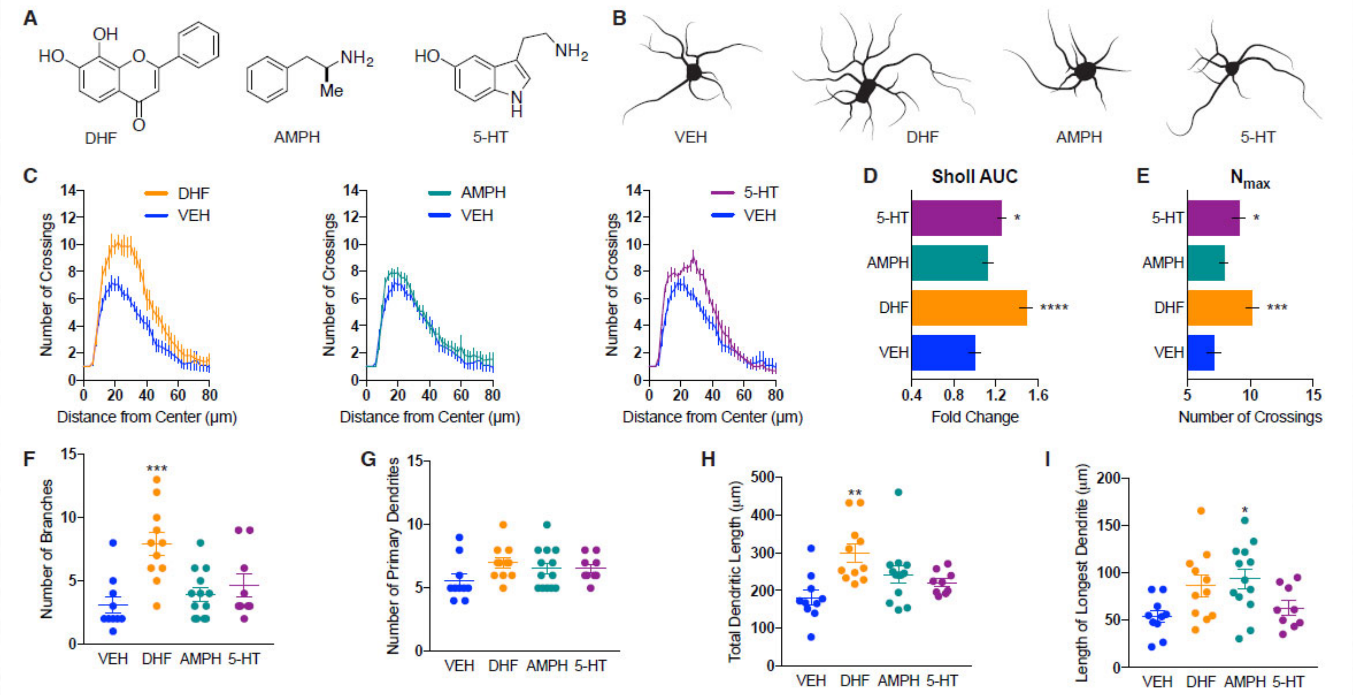

Figure S2. Structural Plasticity is Promoted by a TrkB Agonist, but Not a Psychostimulant or Monoamine Neurotransmitter Structurally Related to Classical Psychedelics, Related to Figure 1. (A) Chemical structures of control compounds used in these studies (DHF = positive control, AMPH and 5HT = negative controls). (B) Representative tracings of cultured embryonic rat cortical neurons (DIV6) treated with compounds. (C) Sholl analysis (circle radii = 2 µm increments) demonstrates that cultured cortical neurons treated with DHF, a TrkB agonist, have more complex dendritic arbors as compared to vehicle control. However, AMPH and 5-HT were not able to elicit a similar response (n = 9-13 neurons per treatment). (D) Area under the curve (AUC) of the Sholl plots in C. (E) Maximum number of crossings (N_{max}) of the Sholl plots in C. (F-I) Cultured cortical neurons treated with DHF, but not AMPH or 5-HT, exhibited an increased number of branch points (F) and total length of the dendritic arbor (H), but minimal changes in the number of primary dendrites (G) or the length of the longest dendrite (I). Error bars represent s.e.m. $*p < 0.05$, $**p < 0.01$, $***p < 0.001$, $****p < 0.0001$ as compared to vehicle control (One-way ANOVA with Dunnett's post-hoc test). VEH = vehicle, AMPH = D-Amphetamine, 5-HT = 5-hydroxytryptamine (serotonin), DHF = 7,8-dihydroxyflavone.

Notably, the anti-addictive alkaloid ibogaine (Alper, 2001; Belgers *et al.*, 2016) was the only psychedelic tested that had absolutely no effect (Figure S4). This was a surprising result because we hypothesized that ibogaine's long-lasting antiaddictive properties might result from its psychoplastogenic properties. Previous work by He *et al.* (2005) clearly demonstrated that ibogaine increases the expression of glial cell linederived neurotrophic factor (GDNF) and that this plasticity-promoting protein is critical to ibogaine's anti-addictive mechanism of action. Because several reports have suggested that noribogaine, a metabolite of ibogaine, might actually be the active compound *in vivo* (Zubaran *et al.*, 1999; Baumann *et al.*, 2000, 2001), we decided to test its ability to promote neuritogenesis in cultured cortical neurons. Gratifyingly, noribogaine robustly increased dendritic arbor complexity with an EC_{50} value comparable to ketamine (Figure S3), providing additional evidence suggesting that it may be the active compound *in vivo*.

To assess the *in vivo* effects of classical psychedelics on neuritogenesis, we started treating *Drosophila* larvae during the first instar with LSD and DOI. As observed in rodent cortical cultures, both LSD and DOI significantly increased dendritic branching of class I sensory neurons; however, they did not increase the total length of the dendritic arbors (Figures 1J-1L). Because of the striking effects of psychedelics on the structures of immature neurons, we hypothesized that they might influence neurodevelopment. To test this, we chronically treated zebrafish embryos with compounds for 6 days immediately following dechorionation and assessed gross morphological changes and behavior. We did not observe any differences in head sizes between the treatment groups, nor did we detect any statistically significant differences in activity levels (Figure S5). Next we assessed the ability of psychedelics to promote neuritogenesis in more mature neurons by starting to treat *Drosophila* larvae during the late second instar. Again, psychedelics increased the branching of class I neurons, although the effect was less dramatic than that observed when treatment was started during the first instar (Figure 1M-1O). Although different developmental stages might be more or less susceptible to the effects of psychedelics, it is also possible that the smaller effect size observed after administering compounds starting at the later time point was simply the result of treating the larvae for a shorter period of time. Regardless, it was quite surprising to observe compound-induced changes in neuronal structure after initiating treatment during the late second instar because class I neurons are stereotyped and typically possess relatively few higher-order branches (Grueber *et al.*, 2002). Moreover, our results demonstrate that psychedelics can promote changes in neuronal structure across vertebrate (rats) and invertebrate (*Drosophila*) species, suggesting that they act through an evolutionarily conserved mechanism.

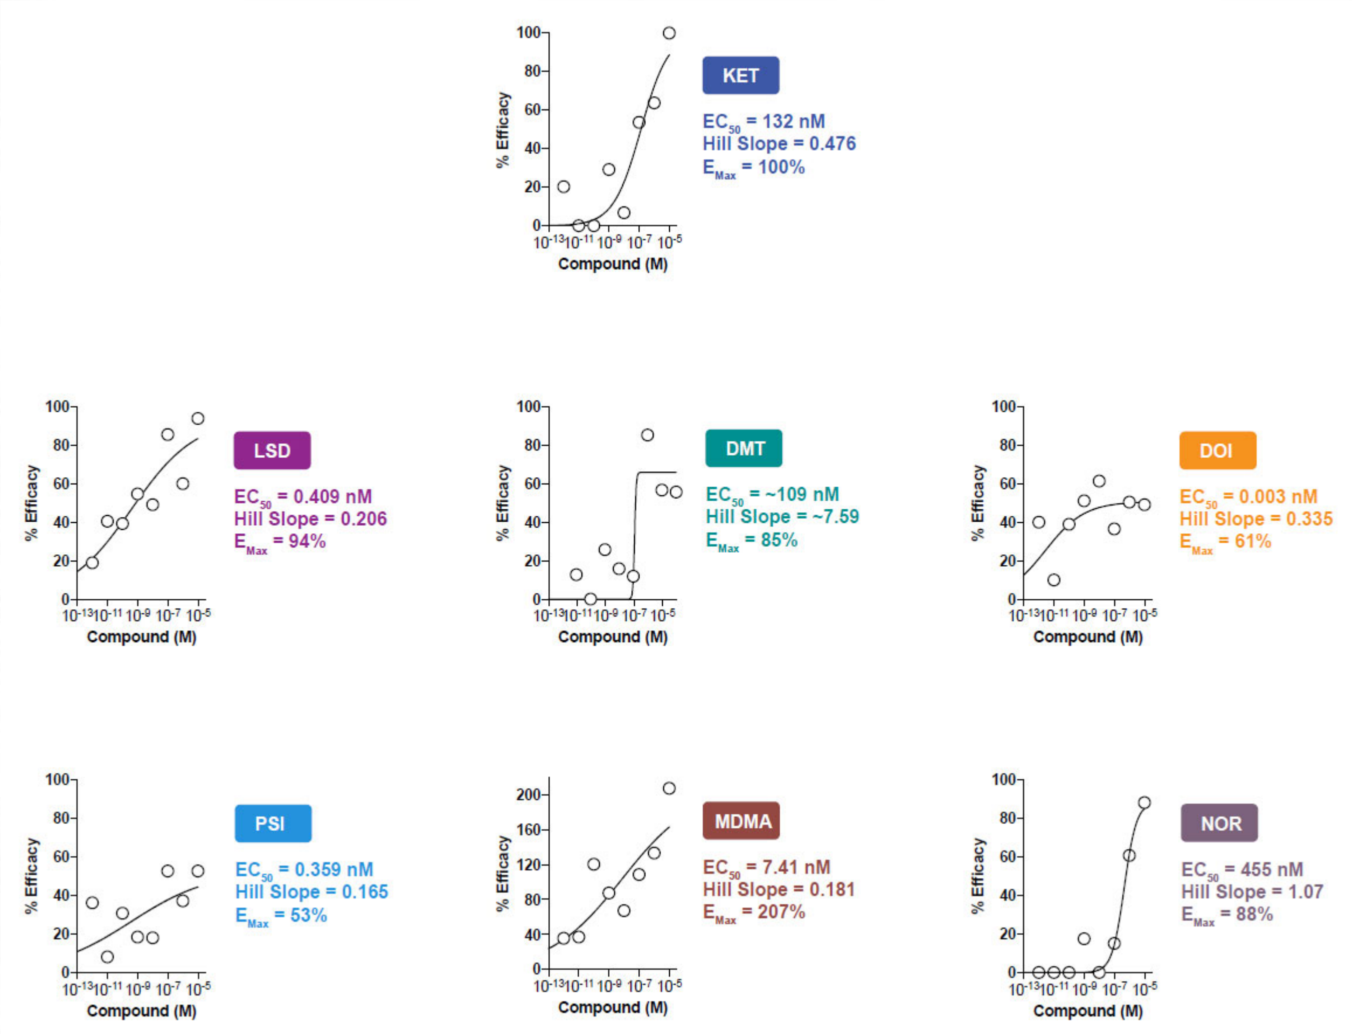

Figure S3. Psychedelics Promote Neuritogenesis in a Dose-Dependent Manner, Related to Figure 1. Cultured embryonic rat cortical neurons (DIV6) were treated with 8 decreasing concentrations of each compound (1Array-fold dilutions) and subjected to Sholl analysis. The N$_{max}$ values obtained following treatment with 1Array µM ketamine and vehicle (Array.1% DMSO) were defined as 1ArrayArray% and Array% respectively. The maximum number of crossings (N$_{max}$) of the Sholl plots are reported relative to these values. Using nonlinear regression analysis, EC$_{5Array}$ values and Hill slopes were calculated. Maximum efficacy relative to 1Array µM ketamine is also shown. Most of the compounds display Hill slopes substantially different from 1, which suggests that this cellular phenotype is not mediated by binding to a single site and implies polypharmacology. KET = ketamine, LSD = lysergic acid diethylamide, DMT = N,N-dimethyltryptamine, DOI = (±)-2,5-dimethoxy-4-iodoamphetamine, PSI = psilocin, MDMA = (±)-3,4-methylenedioxymethamphetamine, NOR = noribogaine.

Psychedelics Promote Spinogenesis and Synaptogenesis

In addition to dendritic atrophy, loss of dendritic spines is a hallmark of depression and other neuropsychiatric disorders (Christoffel *et al.*, 2011; Duman and Aghajanian, 2012), so we next assessed the effects of psychedelics on spinogenesis. We treated mature rat cortical cultures for 24 hr with DOI, DMT, and LSD as representative compounds from the amphetamine, tryptamine, and ergoline classes of psychedelics, respectively. All three compounds increased the number of dendritic spines per unit length, as measured by super-resolution structured illumination microscopy (SIM) (Figures 2A, 2B, and S6), with LSD nearly doubling the number of spines per 10 µm. Additionally, treatment caused a shift in spine morphology, favoring immature (thin and filopodium) over more mature (mushroom) spine types (Figure 2C). Colocalization of pre- and postsynaptic markers following treatment demonstrated that psychedelics promoted synaptogenesis by increasing the density, but not the size of synapses (Figure 2D-2F). This increase in synapse density was accompanied by an increase in the density of VGLUT1 puncta, but not PSD-95 puncta, following compound administration (Figures 2G and 2H).

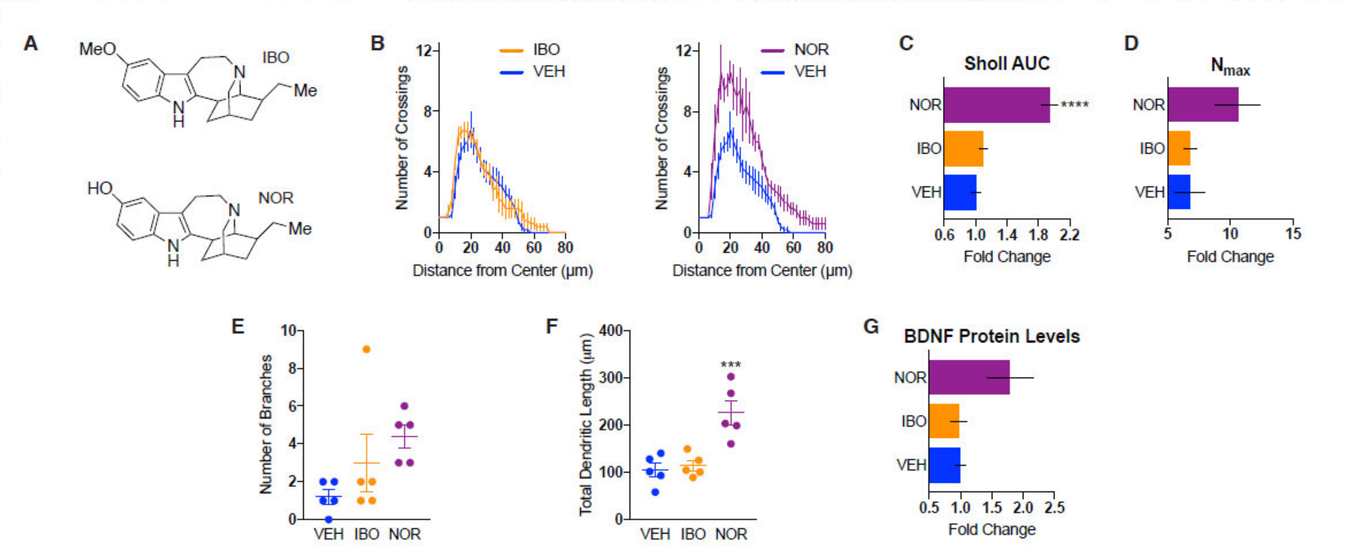

Figure S4. Noribogaine, but Not ibogaine, Promotes Structural Neural Plasticity, Related to Figure 1. (A) Chemical structures of the anti-addictive compound ibogaine and its metabolite noribogaine. (B) Sholl analysis (circle radii = 2 µm increments) demonstrates that cultured embryonic rat cortical neurons (DIV6) treated with noribogaine, but not ibogaine, have more complex dendritic arbors as compared to vehicle control (n = 5 neurons per treatment). (C) Area under the curve (AUC) of the Sholl plots in B. (D) Maximum number of crossings (N_{max}) of the Sholl plots in B. (E-F) Cultured cortical neurons treated with noribogaine, but not ibogaine, exhibited an increased number of branch points (E) and total length of the dendritic arbor (F). (G) Treatment with noribogaine, but not ibogaine, increases BDNF protein levels in DIV18 cultured cortical neurons after 24 h. Error bars represent s.e.m. $*p < 0.05$, $**p < 0.01$, $***p < 0.001$, $****p < 0.0001$ as compared to vehicle control (One-way ANOVA with Dunnett's post-hoc test). VEH = vehicle, IBO = Ibogaine, NOR = Noribogaine.

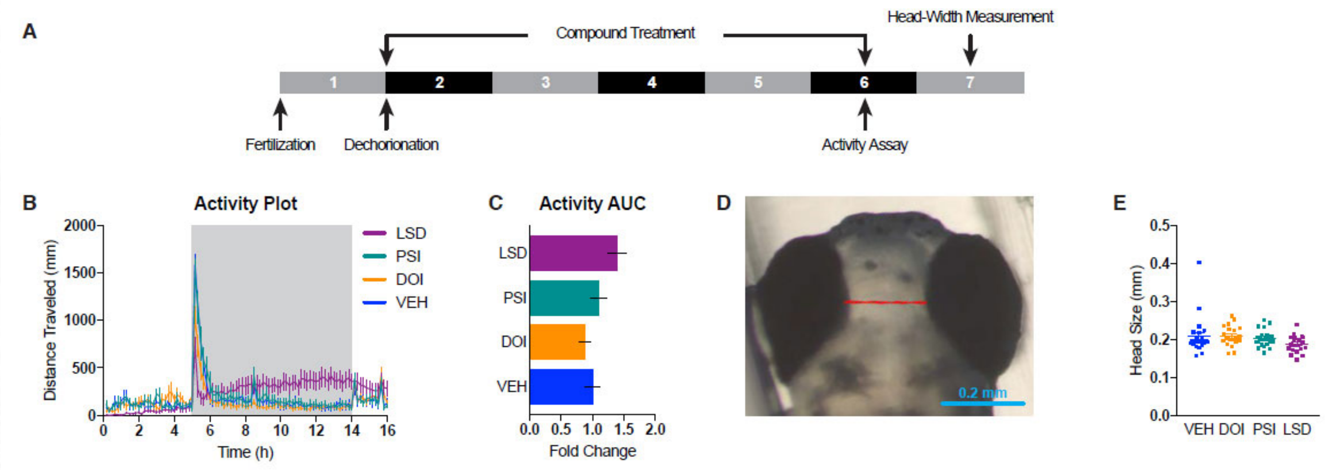

Figure S5. Psychedelics Do Not Induce Behavioral or Gross Morphological Changes in Developing Zebrafish, Related to Figure 1. (A) Experimental design used to assess the effects of psychedelics on zebrafish development. Alternating gray and black blocks represent individual days. Days are numbered in white. (B) Average activity of 5.5 dpf zebrafish (n = 23-24 zebrafish per treatment). The shaded area represents the dark period. A surge in activity immediately followed the transition from light to dark. (C) Area under the curve of the activity plot in B. (D) Representative example of a head-width measurement. (E) Treatment with psychedelics does not affect head size at 6.5 dpf. Error bars represent s.e.m. Treatments did not result in any significant differences as compared to vehicle control (One-way ANOVA with Dunnett's post-hoc test). VEH = vehicle, DOI = (±)-2,5-dimethoxy-4-iodoamphetamine, PSI = Psilocin, LSD = lysergic acid diethylamide, dpf = days post-fertilization.

Encouraged by our *in vitro* results, we next assessed the effects of a single intraperitoneal dose of DMT on spinogenesis in the PFC of adult rats using Golgi-Cox staining. We chose to administer a 10 mg/kg dose of DMT for three reasons. First, all available data suggested that this dose would produce hallucinogenic effects in rats with minimal safety risks (Glennon *et al.*, 1980, 1983; Glennon, 1999; Gatch *et al.*, 2009; Smith *et al.*, 1998; Appel *et al.*, 1999; Winter *et al.*, 2007; Carbonaro *et al.*, 2015; Helsley *et al.*, 1998; Strassman *et al.*, 1994; Nair and Jacob, 2016). Second, we have previously shown that a 10 mg/kg dose of DMT produces positive effects in rat behavioral tests relevant to depression and PTSD (Cameron *et al.*, 2018). Finally, we wanted to directly compare the effects of DMT with ketamine, and seminal studies conducted by Li *et al.* (2010) had previously demonstrated that a 10 mg/kg dose of ketamine produced a robust increase in dendritic spine density in the PFC of rats. We observed a significant increase in the density of dendritic spines on cortical pyramidal neurons 24 hr after dosing with DMT (Figures 2I and 2J). This effect was comparable with that produced by ketamine at the same dose (Figure 2J). Importantly, this DMT-induced increase in dendritic spine density was accompanied by functional effects. *Ex vivo* slice recordings revealed that both the frequency and amplitude of spontaneous excitatory postsynaptic currents (EPSCs) were increased following DMT treatment (Figures 2K-2M). Interestingly, 10 mg/kg and 1 mg/kg doses produced similar responses despite the fact that they are predicted to be hallucinogenic and subhallucinogenic, respectively (Strassman *et al.*, 1994; Nair and Jacob, 2016).

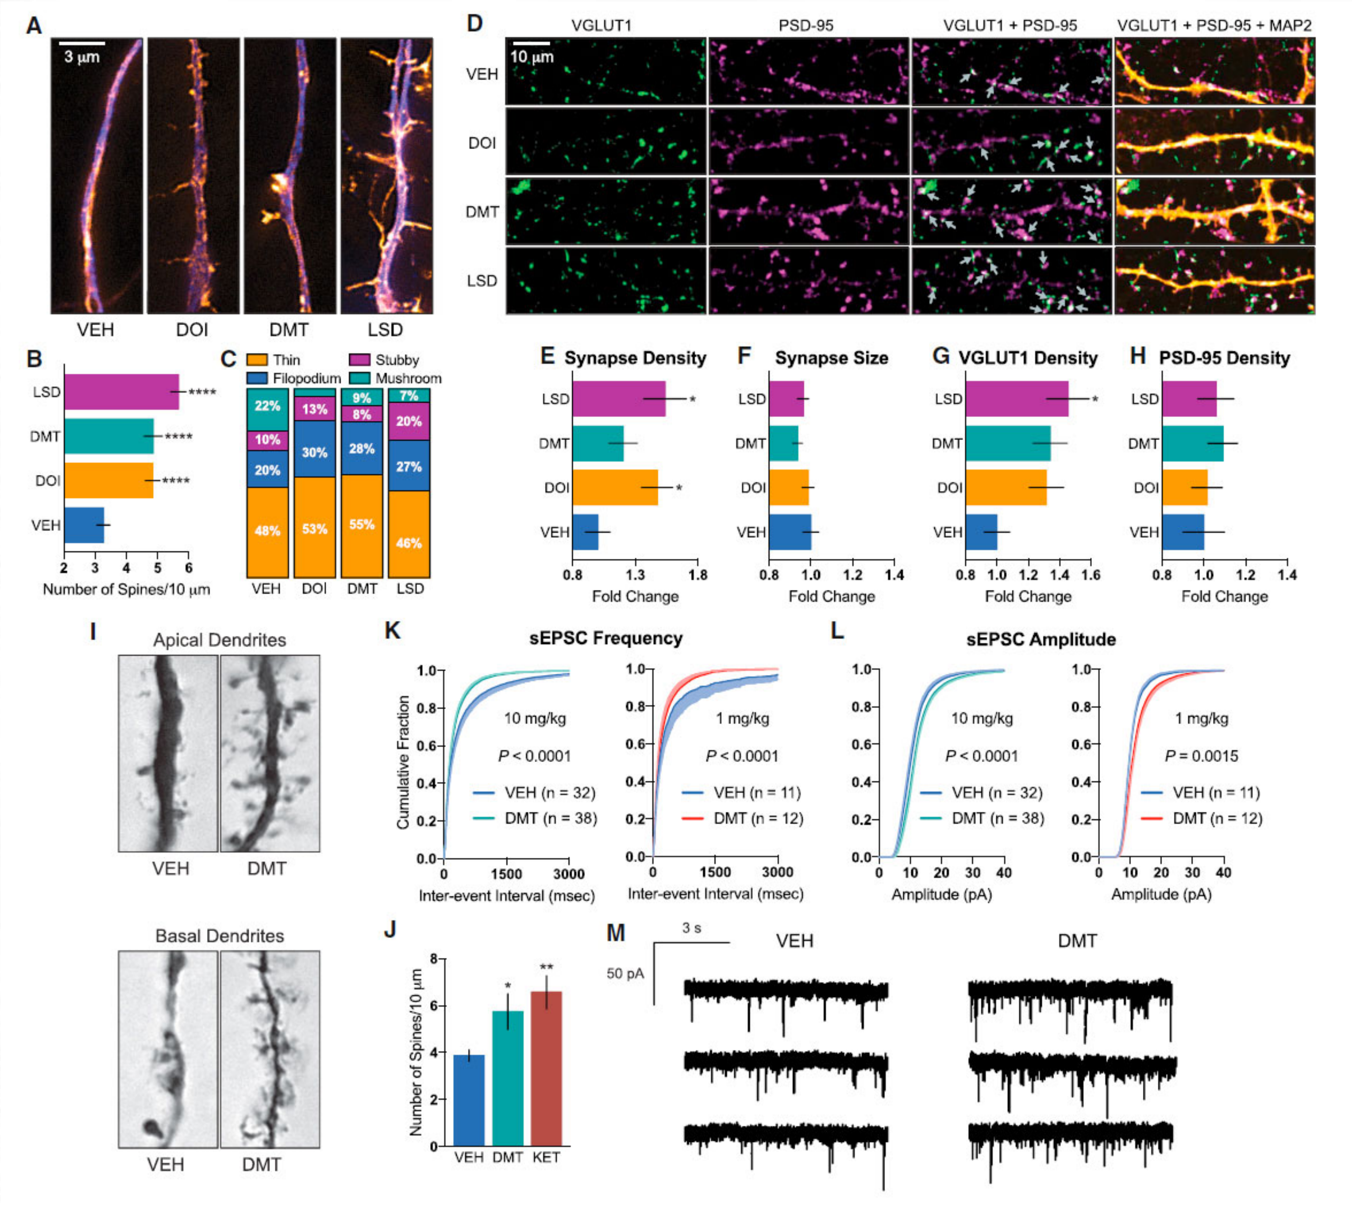

Figure 2. Psychedelics Promote Spinogenesis, Synaptogenesis, and Functional Plasticity
(A) Representative images of cortical neurons (DIV19) treated with compounds for 24 hr, demonstrating that psychedelics increase the number of dendritic spines (blue, MAP2; orange, F-actin).
(B) Quantification of spine density (n = 56-65 neurons).
(C) Relative proportions of spine types following treatment of cortical cultures with psychedelics (n = 16-21 neurons).
(D) Representative images of cortical neurons (DIV19) treated for 24 hr, demonstrating that psychedelics increase synaptogenesis (green, VGLUT1; magenta, PSD-95; yellow, MAP2). White areas in the VGLUT1 + PSD-95 images indicate colocalization of pre- and postsynaptic makers and are indicated by gray arrows.
(E-H) Quantification of synapse density (E), synapse size (F), presynaptic density (VGLUT1) (G), and postsynaptic density (PSD-95) (H) following 24-hr treatment of cortical neurons (DIV19) (n = 39-42 neurons).
(I) Representative images of Golgi-Cox-stained pyramidal neurons from the PFC of rats 24 hr after receiving a 10 mg/kg dose of DMT.
(J) Quantification of spines from (I), demonstrating that DMT (10 mg/kg) increases spinogenesis *in vivo* to a comparable extent as ketamine (10 mg/kg) (n = 11-17 neurons).
(K and L) Whole-cell voltage-clamp recordings of layer V pyramidal neurons from slices obtained 24 hr after DMT treatment (10 mg/kg and 1 mg/kg) demonstrate that DMT increases both spontaneous excitatory postsynaptic current (sEPSC) frequency (K) and amplitude (L) (n = 11-38 neurons from 3 animals).
(M) Representative traces for the 10 mg/kg experiments quantified in (K) and (L). $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, $^{****}p < 0.0001$, as compared to vehicle control (VEH). Data are represented as mean ± SEM. See also Figure S6.

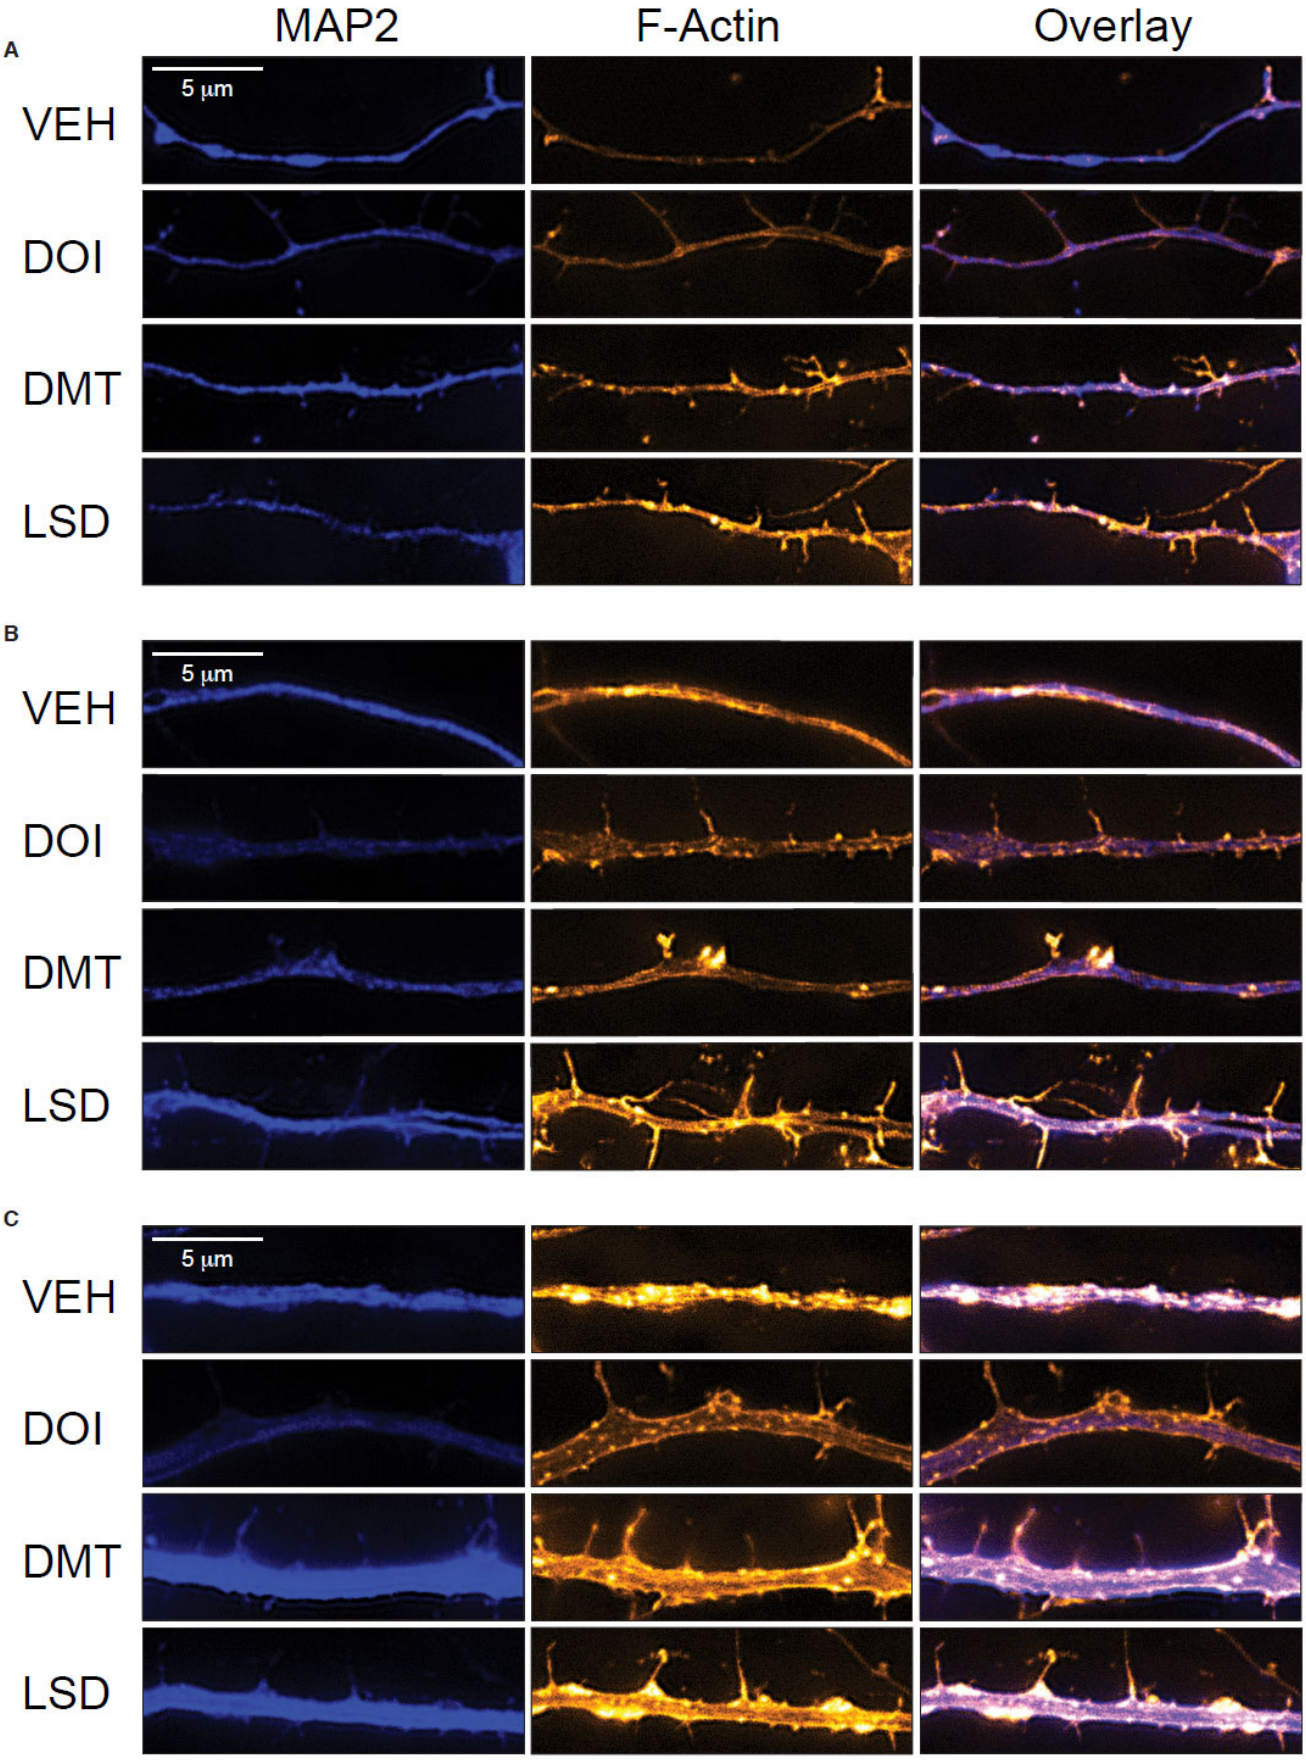

Figure S6. Psychedelics Promote Spinogenesis in Cultured Cortical Neurons, Related to Figure 2. (A-C) Representative super-resolution structured illumination microscopy (SIM) images of cultured embryonic rat cortical neurons (DIV19) treated with compounds for 24 h demonstrate that psychedelics promote spinogenesis (Blue = MAP2, Orange = F-actin). As MAP2 primarily labels the dendritic shaft while F-actin is found in all processes, orange protrusions from the shaft with minimal co-staining indicate dendritic spines. Examples of thin (A), medium (B), and thick (C) dendrites are presented.

Because the half-life of DMT is exceedingly short (~15 min), these results confirm that structural and functional changes induced by DMT persist for hours after the compound has been cleared from the body. Moreover, they demonstrate that DMT produces functional effects on pyramidal neurons of the PFC that mirror those produced by ketamine (Li *et al.*, 2010). Because the PFC is a key brain region involved in extinction learning (Quirk *et al.*, 2006), and both ketamine and DMT have been shown to facilitate fear extinction (Cameron *et al.*, 2018; Girgenti *et al.*, 2017), our results suggest a link between the plasticity-promoting and behavioral effects of these drugs. Because fear extinction can be enhanced by increasing levels of brain-derived neurotrophic factor (BDNF) in the PFC (Peters *et al.*, 2010), and ketamine's behavioral effects have been shown to be BDNF-dependent (Lepack *et al.*, 2014), we next sought to determine the role of BDNF signaling in the plasticity-promoting effects of classical psychedelics.

Psychedelics Promote Plasticity through a TrkBand mTOR-Dependent Mechanism

The role of BDNF in both neuritogenesis and spinogenesis is well known (Cohen-Cory *et al.*, 2010), and several reports suggest that psychedelics are capable of increasing levels of neurotrophic factors (He *et al.*, 2005; Martin *et al.*, 2014; Nichols and Sanders-Bush, 2002; Vaidya *et al.*, 1997). Therefore, we treated cortical neurons with BDNF, DOI, and a combination of the two to see whether they had any additive or synergistic effects. Dose-response studies using recombinant BDNF (Figures 3A-3C) revealed that a 50 ng/mL treatment increased neuritogenesis to a comparable extent as DOI (10 µM). Moreover, a combination of the two did not confer any added benefit, suggesting that they operate through a related mechanism (Figures 3D-3F). Next, we treated cortical neurons with DOI, DMT, and LSD for 24 hr before measuring BDNF gene and protein expression using droplet digital PCR (ddPCR) and ELISA, respectively. Although psychedelics did not increase the expression of *BDNF* transcript (Figure 3G), they did result in a 2-fold increase in BDNF protein levels, although this effect was not statistically significant (Figure 3H). When cortical cultures were co-treated with ANA-12 (Cazorla *et al.*, 2011), a selective antagonist of BDNF's high-affinity receptor TrkB, the ability of psychedelics or BDNF to stimulate neuritogenesis and spinogenesis was completely blocked (Figure 4).

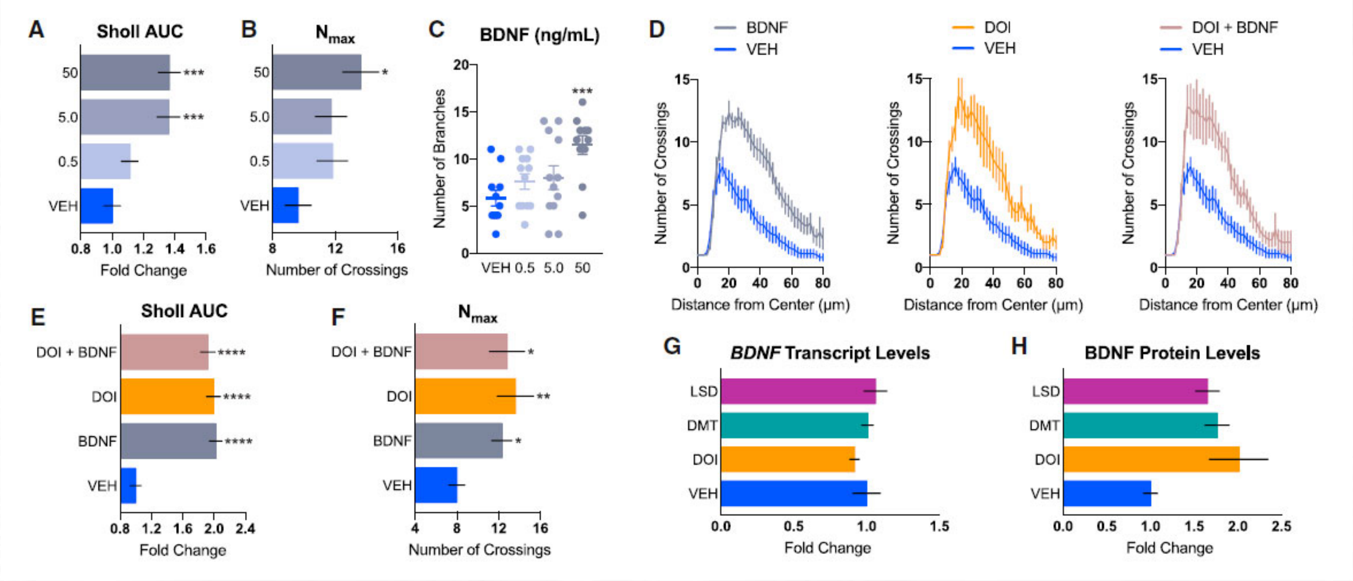

Figure 3. Psychedelics and BDNF Promote Neuritogenesis via a Related Mechanism
(A-C) Dose response of recombinant BDNF on neuritogenesis. AUC of the Sholl plots (A), N_{max} of the Sholl plots (B), and total number of branches (C) of treated cortical neurons (n = 11-12 neurons per treatment, DIV6) indicate that the highest concentration of BDNF (50 ng/mL) is more effective at promoting neuritogenesis than lower concentrations (5.0 and 0.5 ng/mL).
(D) Sholl analysis (n = 5-10 neurons) demonstrating that DOI (10 µM) increases neuritogenesis to a comparable extent as recombinant BDNF (50 ng/mL). A combination of DOI (10 µM) and BDNF (50 ng/mL) did not have any additive or synergistic effects.
(E) AUC of the Sholl plots in (D).
(F) N_{max} of the Sholl plots in (D).
(G and H) Cultured cortical neurons (DIV18) were treated with compounds for 24 hr, and then BDNF gene (G) and protein (H) expression was assessed via ddPCR (n = 4) and ELISA (n = 3-4), respectively. *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, ****$p < 0.0001$, as compared to vehicle control (VEH). Data are represented as mean ± SEM.

Activation of TrkB is known to promote signaling through mTOR (Takei *et al.*, 2004), which plays a key role in structural plasticity (Jaworski *et al.*, 2005; Kumar *et al.*, 2005), the production of proteins necessary for synaptogenesis (Hoeffer and Klann, 2010), and the effects of ketamine (Dwyer and Duman, 2013; Li *et al.*, 2010). Treatment with rapamycin, an mTOR inhibitor, completely blocked psychedelic-induced neuritogenesis (Figure 5), thus confirming that mTOR activation plays a role in the plasticity-promoting effects of classical serotonergic psychedelics.

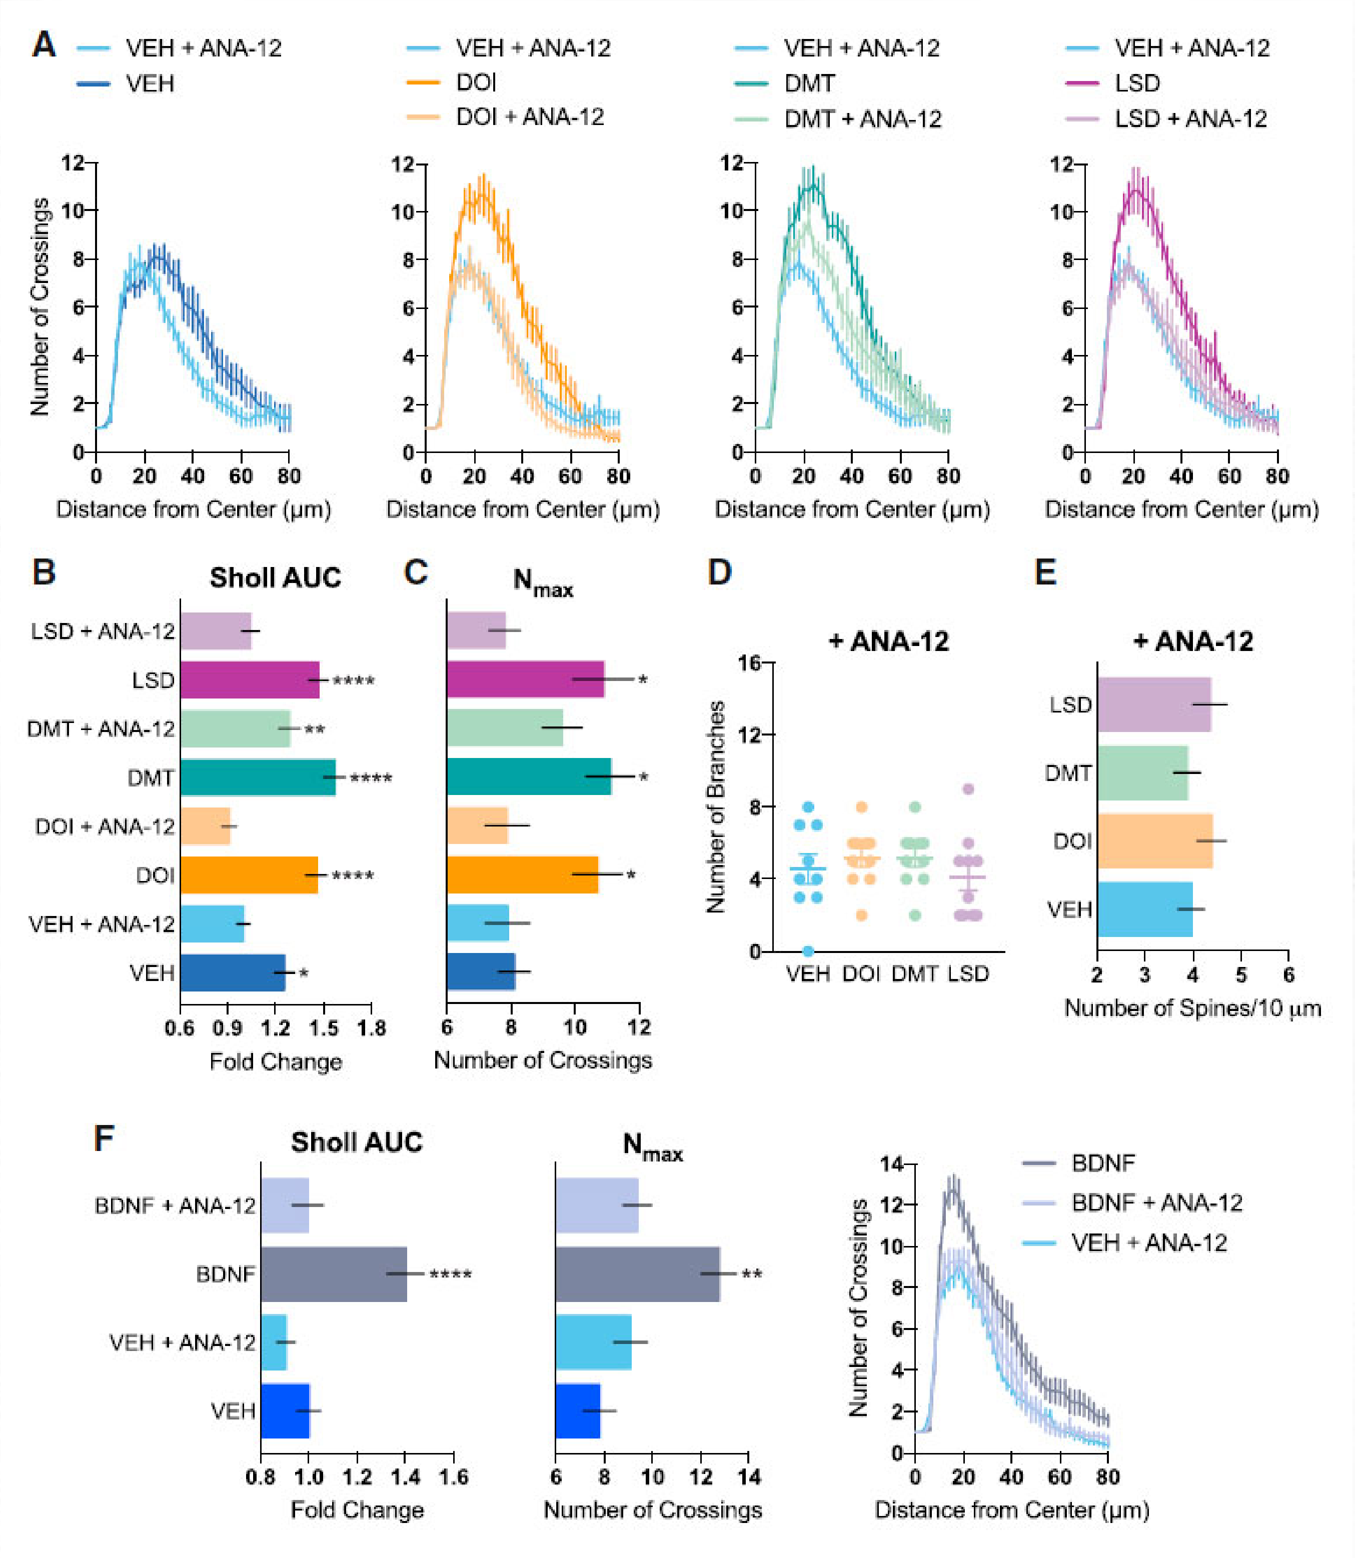

Figure 4. Psychedelic-Induced Changes in Neuronal Structure Are Mediated by TrkB
(A-D) The effects of psychedelics on dendritic arbor complexity are blocked by ANA-12, a selective inhibitor of TrkB, as measured by Sholl analysis of cultured cortical neurons (A) (DIV6). Compound-induced increases in the AUC of the Sholl plots (B), the N_{max} of the Sholl plots (C), and the number of dendritic branches (D) are completely blocked by ANA-12 (n = 8-10 neurons).
(E) The spinogenesis-promoting properties of psychedelics are blocked by ANA-12 (n = 19-21 neurons, DIV19).
(F) Control experiment demonstrating that ANA-12 blocks the effects of BDNF on neuritogenesis (n = 11-15 neurons). $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, $^{****}p < 0.0001$, as compared to vehicle control (VEH) or vehicle + antagonist. Data are represented as mean ± SEM.

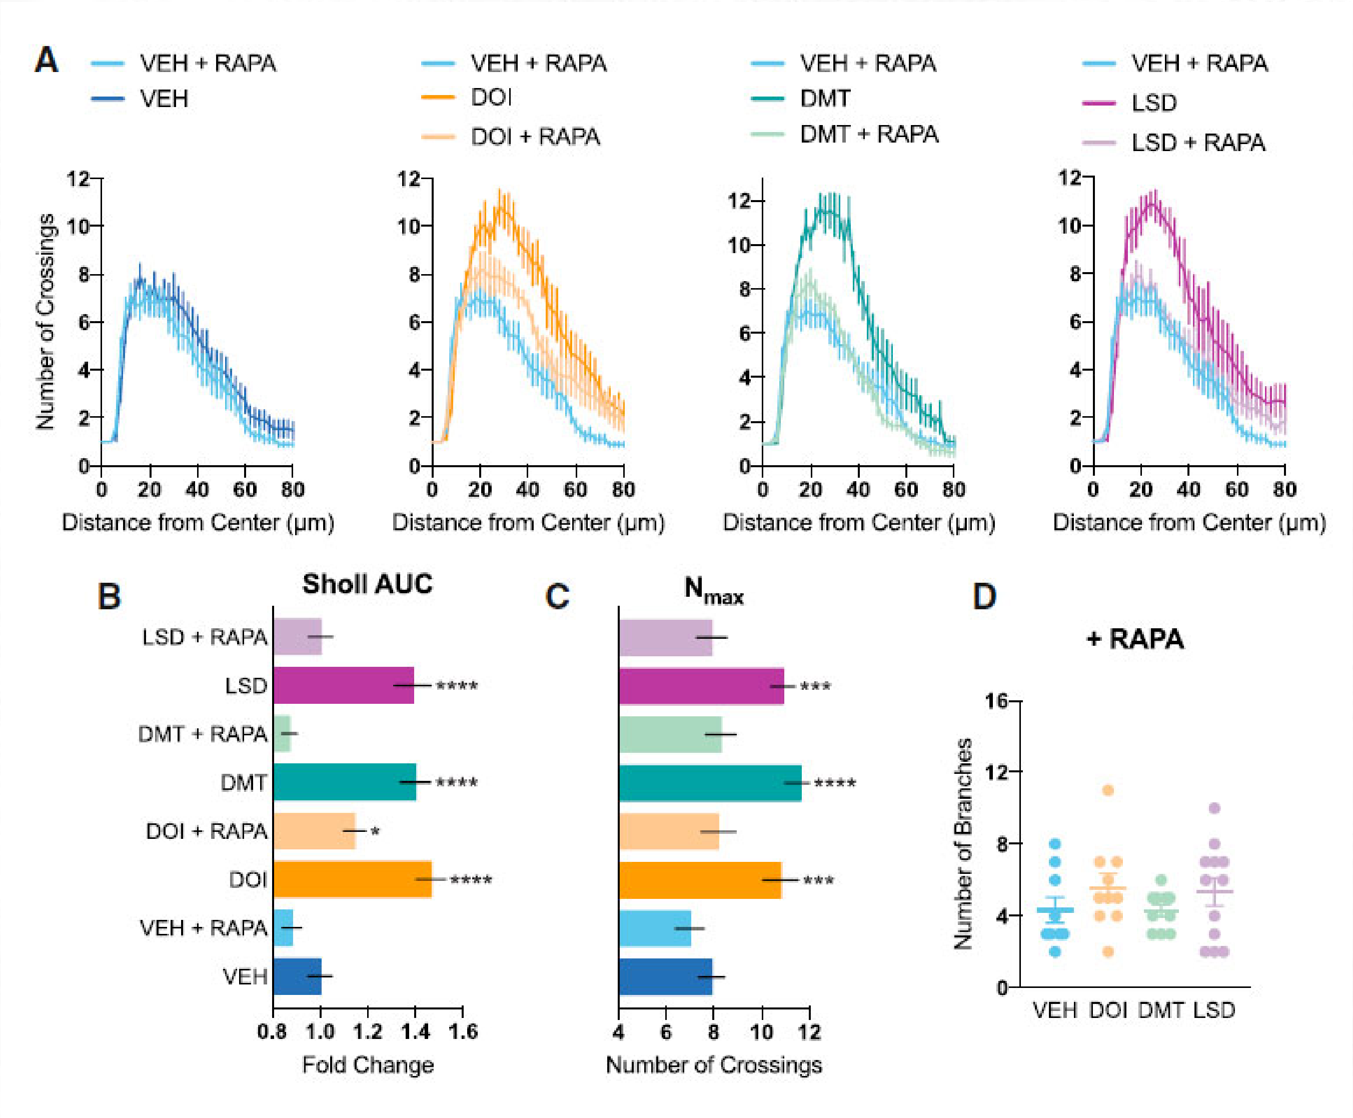

Figure 5. Psychedelic-Induced Changes in Neuronal Structure Are Mediated by mTOR
(A-D) The effects of psychedelics on dendritic arbor complexity are blocked by rapamycin, an inhibitor of mTOR, as measured by Sholl analysis of cultured cortical neurons (A) (DIV6). Compoundinduced increases in the AUC of the Sholl plots (B), the N_{max} of the Sholl plots (C), and the number of dendritic branches (D) are completely blocked by rapamycin (n = 9-12 neurons). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, ****$p < 0.0001$, as compared to vehicle control (VEH) or vehicle + antagonist. Data are represented as mean ± SEM.

The 5-HT2A Receptor Mediates the Effects of Psychedelics on Structural Plasticity

Finally, we sought to determine whether the 5-HT_{2A} receptor played any role in the plasticity-promoting effects of DOI, DMT, and LSD because this receptor is known to be primarily responsible for the hallucinogenic effects of classical psychedelics (Nichols, 2004, 2016). Furthermore, the psychoplastogenic potencies of these and related compounds correlate well with their 5-HT_{2A} receptor affinities (Figure S3) (i.e., a higher 5-HT_{2A} binding affinity generally predicts more potent psychoplastogenic effects). Control experiments demonstrated that 5-HT_{2A} receptors were expressed on cultured rat cortical neurons at both 6 days *in vitro* (DIV6) and DIV19 (Figure 6A). Next we found that co-treatment with ketanserin, a selective 5-HT_{2A} antagonist, completely abrogated the ability of DMT, LSD, and DOI to promote both neuritogenesis and spinogenesis (Figures 6B-6F). Ketanserin was also able to block the effects of psilocin as well as the non-classical psychedelic noribogaine and entactogen MDMA (Figure 6G).

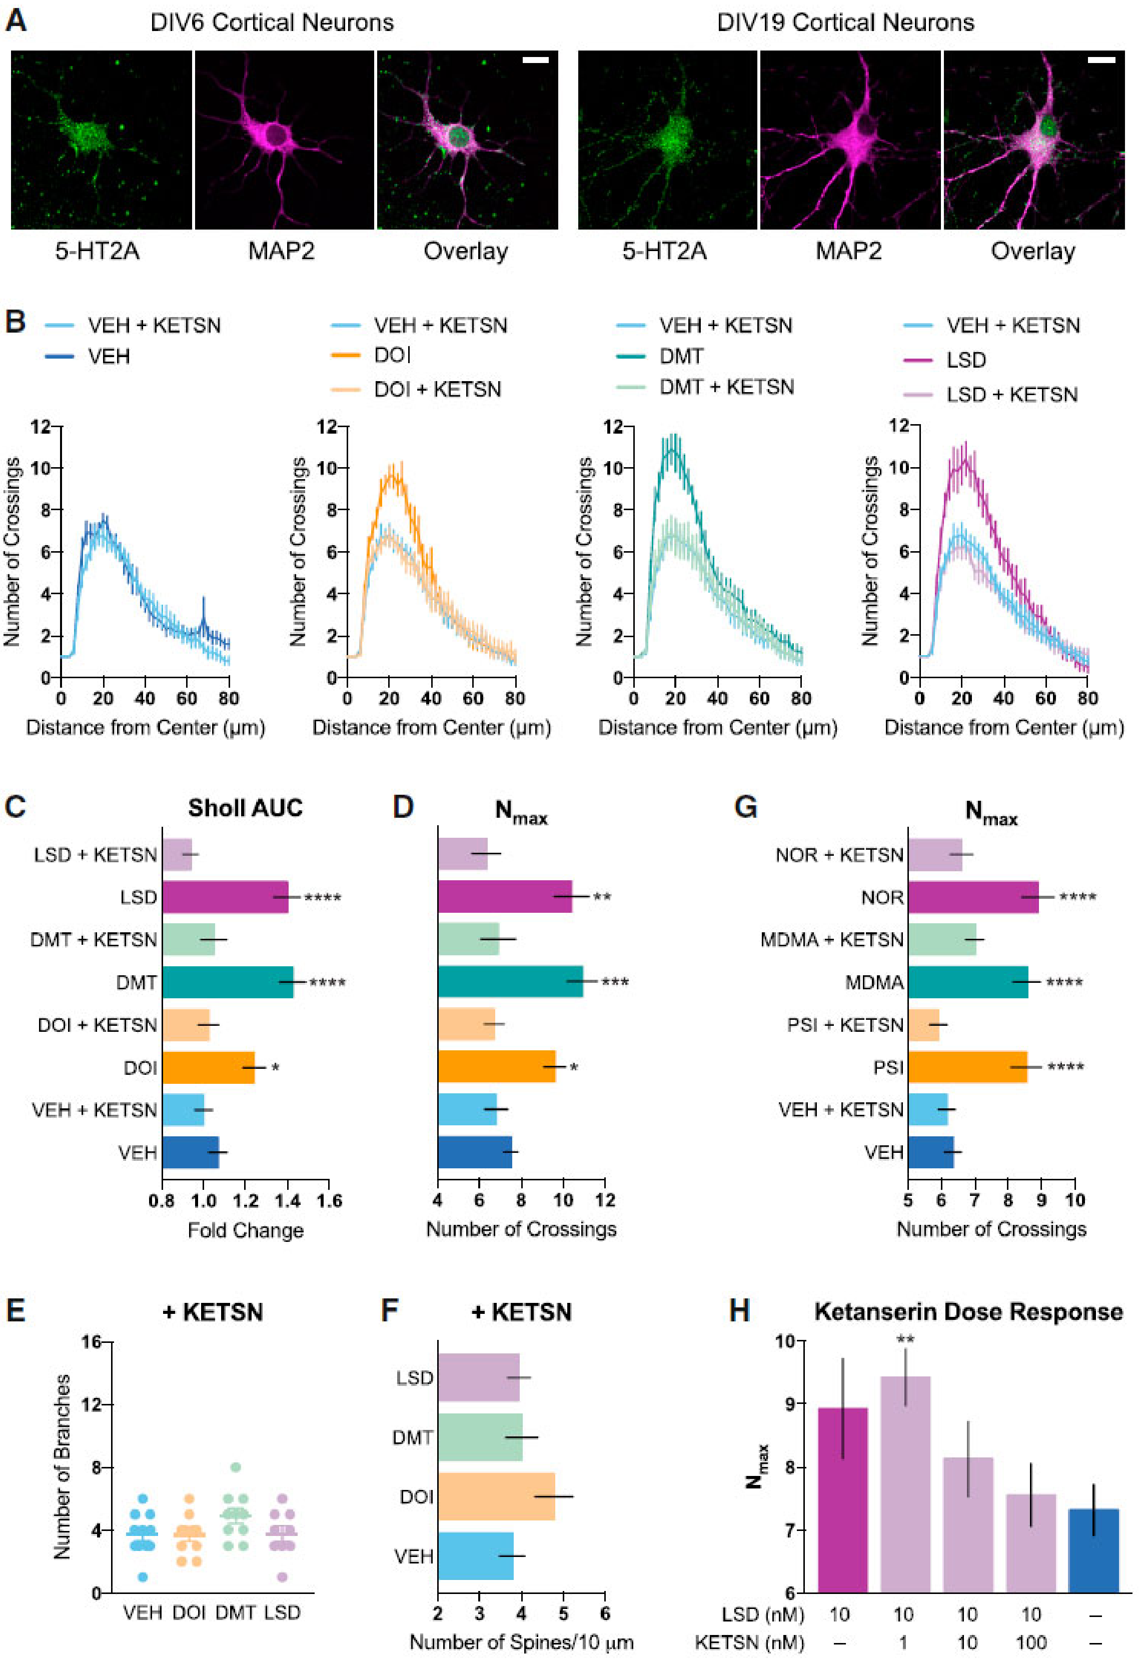

Figure 6. The 5-HT$_{2A}$ Receptor Mediates the Effects of Psychedelics on Structural Plasticity

(A) Rat embryonic cortical neurons express 5-HT$_{2A}$ receptors at both DIV6 and DIV19 (scale bar, 10 μm).

(B) The effects of psychedelics on increasing dendritic arbor complexity are blocked by cotreating with ketanserin, a selective antagonist of 5-HT$_{2A}$ receptors, as measured by Sholl analysis of cultured cortical neurons (DIV6).

(C-E) Compound-induced increases in the AUC of the Sholl plots (C), the N$_{max}$ of the Sholl plots (D), and the number of dendritic branches (E) are completely blocked by ketanserin (n = 10-11 neurons, DIV6).

(F) The spinogenesis-promoting properties of psychedelics are blocked by ketanserin (n = 19-20 neurons, DIV19).

(G) Ketanserin also blocks the increased N$_{max}$ induced by psilocin, noribogaine, and MDMA.

(H) Ketanserin dose-dependently blocks the psychoplastogenic effects of 10 nM LSD (n = 9-38 neurons, DIV6). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, ****$p < 0.0001$, as compared to vehicle control (VEH) or vehicle + antagonist. Data are represented as mean ± SEM.

These initial experiments were performed using doses of psychoplastogens that produced maximal effects on structural plasticity (circa 10 µM) in combination with a 10-fold excess of ketanserin (100 µM). At these concentrations, we could not rule out the possibility of other receptors contributing to the antagonistic effects of ketanserin. Therefore, we treated cultured cortical neurons with a significantly lower dose of LSD (10 nM) and attempted to block its ability to promote neurite outgrowth using increasing doses of ketanserin (Figure 6H). We found that ketanserin blocks the psychoplastogenic effects of LSD by ~50% when treated at 10 nM. This is consistent with the fact that the binding affinities of ketanserin and LSD for the 5-HT$_{2A}$ receptor are roughly equivalent (low nanomolar). Increasing the concentration of ketanserin to 100 nM, 10-fold higher than the concentration of LSD used in this experiment, completely prevented LSD-induced neuritogenesis. At 100 nM, ketanserin is relatively selective for the 5-HT$_{2A}$ receptor, although, at this concentration, we cannot rule out the possible involvement of 5-HT$_{2C}$, adrenergic, or histamine receptors.

As a final note, the concentration responses of most psychoplastogens had Hill slopes that deviated from 1.0 (Figure S3), implying polypharmacology. Because psychedelics have relatively high affinities for 5-HT$_{2A}$ receptors, it is likely that the effects of psychedelics are mediated primarily through 5-HT$_{2A}$ receptors at low concentrations and modulated by other targets at high concentrations. Interestingly, the concentration response of DMT was the only one to exhibit a Hill slope greater than 1.0, indicating some form of cooperativity.

Discussion

Classical serotonergic psychedelics are known to cause changes in mood (Griffiths *et al.*, 2006, 2008, 2011) and brain function (Carhart-Harris *et al.*, 2017) that persist long after the acute effects of the drugs have subsided. Moreover, several psychedelics elevate glutamate levels in the cortex (Nichols, 2004, 2016) and increase gene expression *in vivo* of the neurotrophin *BDNF* as well as immediate-early genes associated with plasticity (Martin *et al.*, 2014; Nichols and Sanders-Bush, 2002; Vaidya *et al.*, 1997). This indirect evidence has led to the reasonable hypothesis that psychedelics promote structural and functional neural plasticity, although this assumption had never been rigorously tested (Bogenschutz and Pommy, 2012; Vollenweider and Kometer, 2010). The data presented here provide direct evidence for this hypothesis, demonstrating that psychedelics cause both structural and functional changes in cortical neurons.

Prior to this study, two reports suggested that psychedelics might be able to produce changes in neuronal structure. Jones *et al.* (2009) demonstrated that DOI was capable of transiently increasing the size of dendritic spines on cortical neurons, but no change in spine density was observed. The second study showed that DOI promoted neurite extension in a cell line of neuronal lineage (Marinova *et al.*, 2017). Both of these reports utilized DOI, a psychedelic of the amphetamine class. Here we demonstrate that the ability to change neuronal structure is not a unique property of amphetamines like DOI because psychedelics from the ergoline, tryptamine, and iboga classes of compounds also promote structural plasticity. Additionally, D-amphetamine does not increase the complexity of cortical dendritic arbors in culture, and therefore, these morphological changes cannot be simply attributed to an increase in monoamine neurotransmission.

The identification of psychoplastogens belonging to distinct chemical families is an important aspect of this work because it suggests that ketamine is not unique in its ability to promote structural and functional plasticity. In addition to ketamine, the prototypical psychoplastogen, only a relatively small number of plasticity-promoting small molecules have been identified previously. Such compounds include the *N*-methyl-D-aspartate (NMDA) receptor ligand GLYX-13 (i.e., rapastinel), the mGlu2/3 antagonist LY341495, the TrkB agonist 7,8-DHF, and the muscarinic receptor antagonist scopolamine (Lepack *et al.*, 2016; Castello *et al.*, 2014; Zeng *et al.*, 2012; Voleti *et al.*, 2013). We observe that hallucinogens from four distinct structural classes (i.e., tryptamine, amphetamine, ergoline, and iboga) are also potent psychoplastogens, providing additional lead scaffolds for medicinal chemistry efforts aimed at identifying neurotherapeutics. Furthermore, our cellular assays revealed that several of these compounds were more efficacious (e.g., MDMA) or more potent (e.g., LSD) than ketamine. In fact, the plasticity-promoting properties of psychedelics and entactogens rivaled that of BDNF (Figures 3A-3C and S3). The extreme potency of LSD in particular might be due to slow off kinetics, as recently proposed following the disclosure of the LSD-bound 5-HT$_{2B}$ crystal structure (Wacker *et al.*, 2017).

Importantly, the psychoplastogenic effects of psychedelics in cortical cultures were also observed *in vivo* using both vertebrate and invertebrate models, demonstrating that they act through an evolutionarily conserved mechanism. Furthermore, the concentrations of psychedelics utilized in our *in vitro* cell culture assays were consistent with those reached in the brain following systemic administration of therapeutic doses in rodents (Yang *et al.*, 2018; Cohen and Vogel, 1972). This suggests that neuritogenesis, spinogenesis, and/or synaptogenesis assays performed using cortical cultures might have value for identifying psychoplastogens and fast-acting antidepressants. It should be noted that our structural plasticity studies performed *in vitro* utilized neurons exposed to psychedelics for extended periods of time. Because brain exposure to these compounds is often of short duration due to rapid metabolism, it will be interesting to assess the kinetics of psychedelic-induced plasticity.

A key question in the field of psychedelic medicine has been whether or not psychedelics promote changes in the density of dendritic spines (Kyzar *et al.*, 2017). Using super-resolution SIM, we clearly demonstrate that psychedelics do, in fact, increase the density of dendritic spines on cortical neurons, an effect that is not restricted to a particular structural class of compounds. Using DMT, we verified that cortical neuron spine density increases *in vivo* and that these changes in structural plasticity are accompanied by functional effects such as increased amplitude and frequency of spontaneous EPSCs. We specifically designed these experiments to mimic previous studies of ketamine (Li *et al.*, 2010) so that we might directly compare these two compounds, and, to a first approximation, they appear to be remarkably similar. Not only do they both increase spine density and neuronal excitability in the cortex, they seem to have similar behavioral effects. We have shown previously that, like ketamine, DMT promotes fear extinction learning and has antidepressant effects in the forced swim test (Cameron *et al.*, 2018). These results, coupled with the fact that ayahuasca, a DMT-containing concoction, has potent antidepressant effects in humans (Osório *et al.*, 2015; Sanches *et al.*, 2016; Santos *et al.*, 2007), suggests that classical psychedelics and ketamine might share a related therapeutic mechanism.

Although the molecular targets of ketamine and psychedelics are different (NMDA and 5-HT$_{2A}$ receptors, respectively), they appear to cause similar downstream effects on structural plasticity by activating mTOR. This finding is significant because ketamine is known to be addictive whereas many classical psychedelics are not (Nutt *et al.*, 2007, 2010). The exact mechanisms by which these compounds stimulate mTOR is still not entirely understood, but our data suggest that, at least for classical psychedelics, TrkB and 5-HT$_{2A}$ receptors are involved. Although most classical psychedelics are not considered to be addictive, there are still significant safety concerns with their use in medicine because they cause profound perceptual disturbances and still have the potential to be abused. Therefore, the identification of non-hallucinogenic analogs capable of promoting plasticity in the PFC could facilitate a paradigm shift in our approach to treating neuropsychiatric diseases. Moreover, such compounds could be critical to resolving the long-standing debate in the field concerning whether the subjective effects of psychedelics are necessary for their therapeutic effects (Maji&cacute; *et al.*, 2015). Although our group is actively investigating the psychoplastogenic properties of non-hallucinogenic analogs of psychedelics, others have reported the therapeutic potential of safer structural and functional analogs of ketamine (Moskal *et al.*, 2017; Yang *et al.*, 2015; Zanos *et al.*, 2016).

Our data demonstrate that classical psychedelics from several distinct chemical classes are capable of robustly promoting the growth of both neurites and dendritic spines *in vitro*, *in vivo*, and across species. Importantly, our studies highlight the similarities between the effects of ketamine and those of classical serotonergic psychedelics, supporting the hypothesis that the clinical antidepressant and anxiolytic effects of these molecules might result from their ability to promote structural and functional plasticity in prefrontal cortical neurons. We have demonstrated that the plasticity-promoting properties of psychedelics require TrkB, mTOR, and 5-HT$_{2A}$ signaling, suggesting that these key signaling hubs may serve as potential targets for the development of psychoplastogens, fast-acting antidepressants, and anxiolytics. Taken together, our results suggest that psychedelics may be used as lead structures to identify next-generation neurotherapeutics with improved efficacy and safety profiles.

Experimental Procedures

Drugs

For *in vitro* studies, all compounds were dissolved in DMSO and diluted 1:1,000, with the exception that BDNF was dissolved in water. Cells were treated with DMT at a final concentration of 90 µM (0.1% DMSO), whereas all other compounds were used at 10 µM (0.1% DMSO) unless noted otherwise. For *in vivo* studies, DMT or ketamine was dissolved in sterile 0.9% saline and administered intraperitoneally at a dose of 10 mg/kg and an injection volume of 1 mL/kg.

Animals

Sprague-Dawley rats were obtained from Charles River Laboratories (Wilmington, MA, USA). The age and sex of the animals used are noted under each individual experimental subheading. All experimental procedures involving animals were approved by the University of California, Davis Institutional Animal Care and Use Committee (IACUC) and adhered to the principles described in the NIH Guide for the Care and Use of Laboratory Animals. The University of California, Davis is accredited by the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC) and has an Animal Welfare Assurance number (A3433-01) on file with the Office of Laboratory Animal Welfare (OLAW).

Cell Culture

Primary cortical cultures were prepared using tissue from embryonic day 18 (E18) Sprague-Dawley rats. Cells were plated at various densities on poly-Dlysine-coated plates depending on the specific experiment (Supplemental Experimental Procedures). Plating medium consisted of 10% heat-inactivated fetal bovine serum (FBS) (Life Technologies), 1% penicillin-streptomycin (Life Technologies), and 0.5 mM glutamine (Life Technologies) in Neurobasal (Life Technologies). After 15-24 hr, the medium was removed and exchanged for replacement medium containing 13 B27 supplement (Life Technologies), 1% penicillin-streptomycin, 0.5 mM glutamine, 12.5 µM glutamate, and Neurobasal. After 96 hr, 50% of the medium was removed and replaced with feed medium containing 13 B27 supplement, 1% penicillin-streptomycin, and 0.5 mM glutamine. Once per week, until the cultures had reached sufficient maturity for experiments, 50% of the culture medium was removed and replaced with feed medium, with an additional 20% by volume being added to account for evaporation. For experiments using antagonists or inhibitors, cells were pretreated with ANA-12 (10 µM), rapamycin (100 nM), and ketanserin (100 µM) for 10 min prior to addition of test compounds unless otherwise noted. The final DMSO concentration of these experiments was 0.2%. The neurons used in each cellular experiment were taken from at least two different treatment wells, and the wells were randomized to account for plate effects. All of the cellular experiments were replicated on at least two occasions by two or more experimenters.

Statistical Analysis

Appropriate samples sizes were estimated based on our previous experiences performing similar experiments. Data are represented as mean ± SEM. Statistical analyses were performed using GraphPad Prism (version 7.0a). For analyses involving comparison of three or more groups, a one-way analysis of variance (Dunnett's *post hoc* test) was utilized. No statistics were calculated for the individual points of the Sholl plots. Instead, statistical analyses were performed on the aggregate data (i.e., the area under the curve of the Sholl plot). Probability distributions from electrophysiology experiments were compared using a Kolmogorov-Smirnov test. $^*p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, and $^{****}p < 0.0001$ compared with vehicle control or vehicle + antagonist.

Acknowledgments

We thank Lee E. Dunlap for synthesizing DMT, Aurora Martinez-Horta for assistance with Golgi-Cox staining experiments, the Light Microscopy Imaging Facility in the Department of Molecular and Cellular Biology for the use of their Nikon N-SIM, Javier González-Maeso for providing 198A2 cells, and members of the Olson laboratory for discussions regarding the manuscript. We also thank Valentina Popescu in the Department of Classics at UC Davis for assistance with coining the term ''psychoplastogen.'' Several antibodies were generously provided by the Stanley Center for Psychiatric Research at the Broad Institute. This work was supported by funds from the UC Davis Department of Chemistry and Department of Biochemistry and Molecular Medicine, a UC Davis Provost's Undergraduate Fellowship (to A.C.G.), a UC Davis MIND Institute IDDRC grant U54 HD079125 (to M.Y.D. and K.B.), an Alfred P. Sloan Fellowship (FG-2016-6814 to M.Y.D.), and NIH grants T32GM113770 (to C.L.) and 5T32MH082174-09 (to L.P.C. and E.B.).

Author Contributions

D.E.O., C.L., and A.K.M. were responsible for the overall experimental design. C.L. performed the majority of the neuritogenesis, spinogenesis, synaptogenesis, and biochemical experiments described, with A.C.G. and S.S.Z. providing assistance. C.L., L.P.C., and D.E.O. performed the Golgi-Cox staining experiments. L.P.C., J.M.W., and E.V.B. performed the electrophysiology experiments, with J.A.G. supervising these studies. K.M.O.-M. and P.C.W. performed the experiments in *Drosophila*. M.Y.D. and K.F.B. performed the zebrafish experiments. A.S. developed the program for analyzing synapse number and size. M.R.P. supervised the SIM experiments. W.C.D. performed 5-HT$_{2A}$ expression studies and assisted with fluorescence microscopy data analysis. D.E.O. conceived the project, supervised the experiments, and wrote the manuscript with input from all authors.

Declaration of Interests

D.E.O. has submitted a patent application related to this work (PCT/US2017/ 054277).

Supplemental Information

Supplemental Methods

Drugs

The NIH Drug Supply Program provided (±)-2,5-dimethoxy-4-iodoamphetamine (DOI), lysergic acid diethylamide (LSD), ibogaine (IBO), noribogaine (NOR), (±)-3,4-metheylendioxymethamphetamine (MDMA), psilocin (PSI), and D-amphetamine (AMPH). Other chemicals were purchased from commercial sources such as ketamine hydrochloride (KET, Fagron), serotonin hydrochloride (5-HT, Alfa Aesar), 7,8-dihydroxyflavone (DHF, TCI), ANA-12 (MedChem Express), rapamycin (RAPA, Alfa Aesar), ketanserin (KETSN, ApexBio), and brain-derived neurotrophic factor (BDNF, Sigma-Aldrich). The fumarate salt of *N,N*-dimethyltryptamine (DMT), was synthesized in house as described previously (Cameron *et al.*, 2018) and judged to be analytically pure based on NMR and LC-MS data.

Neuritogenesis Experiments

After 3 days *in vitro* (DIV3), approximately 50,000 cells/well in poly-D-lysine coated 24 well plates were treated. Treatment was accomplished by first diluting DMSO stock solutions of compounds 1:10 in Neurobasal followed by a 1:100 dilution into each well (total dilutio*n* = 1:1000). After 72 h, cells were fixed by removing 80% of the media and replacing it with a volume of 4% aqueous paraformaldehyde (Alfa Aesar) equal to 50% of the working volume of the well. Then, the cells were allowed to sit for 20 min at room temperature before the fixative was aspirated and each well washed twice with DPBS. Cells were permeabilized using 0.2% Triton X-100 (ThermoFisher) in DPBS for 20 minutes at room temperature without shaking. Plates were blocked with antibody diluting buffer (ADB) containing 2% bovine serum albumin (BSA) in DPBS for 1 h at room temperature. Then, plates were incubated overnight at 4°C with gentle shaking in ADB and a chicken anti-MAP2 antibody (1:10,000; EnCor, CPCA-MAP2). The next day, plates were washed three times with DPBS and once with 2% ADB in DPBS. Plates were incubated for 1 h at room temperature in ADB containing an anti-chicken IgG secondary antibody conjugated to Alexa Fluor 488 (Life Technologies, 1:500) and washed five times with DPBS. After the final wash, 500 µL of DPBS was added per well and imaged on a Leica inverted epifluorescence microscope at 40x magnification. Images were analyzed using the Simple Neurite Tracer and Sholl analysis plug-ins for ImageJ Fiji (version 1.51N). Sholl analysis circle radii = 2 µm increments. All images were taken and analyzed by an experimenter blinded to treatment conditions.

For the dose response experiments (Figure S3) and two of the ketanserin blocking experiments (Figure 6G and H), a slightly modified method was employed. Neurons were cultured at approximately 15,000 cells/well in poly-D-lysine coated 96-well plates. For the dose response studies, neurons were treated at DIV3 by removing 10% of the media and replacing that with a 10x solution of compound in Neurobasal to reach the desired concentrations (final concentration of DMSO = 0.1%). For the ketanserin blocking experiments, the media was replaced on DIV3 with "replacement media" containing ketanserin. After 10 mins, compounds dissolved in Neurobasal were added to yield final concentrations of experimental compound and ketanserin (final concentration of DMSO = 0.2%). On DIV6, cells were fixed and imaged as described above. Plates were imaged on a Molecular Devices ImageXpress Micro XLS Widefield High-Content Analysis System at 9 sites per well using 20x magnification. Images were analyzed using ImageJ Fiji (version 1.51N). All analysis was done by an experimenter blinded to treatment conditions.

Spinogenesis Experiments

Cells were plated at a density of 35,000 cells/well on glass coverslips in 24 well plates. At DIV18, cells were treated for 24 h and fixed as described for the neuritogenesis experiments (vide supra). Fixative was aspirated and each well washed twice with DPBS. Cells were permeabilized using 0.2% Triton X-100 (ThermoFisher) in DPBS for 20 minutes at room temperature without shaking. Plates were blocked with antibody diluting buffer (ADB) containing 2% bovine serum albumin (BSA) in DPBS for 1 h at room temperature. Then, plates were incubated overnight at 4°C with gentle shaking in ADB and anti-chicken MAP2 (1:10,000; EnCor, CPCA-

MAP2). The next day, plates were washed three times with DPBS and once with 2% ADB in DPBS. Plates were incubated for 1 h at room temperature in ADB containing an anti-chicken IgG secondary antibody conjugated to Alexa Fluor 568 (Life Technologies, 1:500) and phalloidin conjugated to Alexa Fluor 488 (Life Technologies, 1:40). Then, the cells were washed five times with DPBS. Finally, the coverslips were mounted onto microscope slides using ProLong Gold (Life Technologies) and allowed to cure for 24 hours at room temperature. Images of secondary dendrites were taken using a Nikon N-SIM Structured Illumination Super-resolution Microscope with a 100x/NA 1.49 objective, 100 EX V-R diffraction grating, and an Andor iXon3 DU-897E EMCCD. Images were recollected and reconstructed in the "2D-SIM" mode (no out of focus light removal; reconstruction used three diffraction grating angles each with three translations). Dendritic spines were counted manually by a trained experimenter who was blinded to the treatment conditions.

Synaptogenesis Experiments

Cells were plated at a density of 35,000 cells/well on glass coverslips in 24 well plates. At DIV18, cells were treated for 24 h and fixed as described for the neuritogenesis experiments (vide supra). Fixative was aspirated and each well washed twice with DPBS. Cells were permeabilized using 0.2% Triton X-100 (ThermoFisher) in DPBS for 20 minutes at room temperature without shaking. Plates were blocked with antibody diluting buffer (ADB) containing 2% bovine serum albumin (BSA) in DPBS for 1 h at room temperature. Then, plates were incubated overnight at 4°C with gentle shaking in ADB and anti-MAP2 (1:10,000; EnCor, CPCA-MAP2), anti-VGLUT1 (Millipore, AB5905, 1:1000), and anti-PSD-95 (Millipore, MABN68, 1:500) antibodies. The next day, plates were washed three times with DPBS and once with 2% ADB in DPBS. Plates were incubated for 1 h at room temperature in ADB containing secondary antibodies conjugated to Alexa Fluor 488 (Life Technologies, 1:500), Cy3 (Jackson ImmunoResearch Inc, 1:500), or Alexa Fluor 647 (Jackson ImmunoResearch Inc, 1:500). Images of secondary dendrites were collected using a confocal microscope (Olympus FV1000) with a 60x oil objective and a 1.42 numerical aperture.

Synaptic density and size as well as PSD-95 and VGLUT1 densities were determined using custom software that works in three stages. The first stage is a foreground/background separation that outputs a mask of pixels within the image that correspond to the neuron. Next, puncta of synaptic proteins are identified using only pixels belonging to the foreground mask from the first stage. Finally, synapses are identified as colocalizations of puncta of pre- and post-synaptic proteins. The foreground mask is determined using a fluorescence intensity threshold chosen to maximize the connectedness of both the foreground and the background. Specifically, for a given threshold, connected pixels that pass the threshold are clustered together, and connected pixels that fall below threshold are clustered together. The average cluster size is computed for each type of cluster, and the threshold that maximizes the product of these averages is chosen. The resulting foreground mask is cleaned by removing clusters smaller than 0.06 μm^2 and smoothed by eliminating pixels connected to fewer than three other pixels that passed the threshold and adding pixels connected to more than four pixels that passed the threshold. Within the foreground mask, every pixel that has greater intensity than its neighbors is treated as a seed point for a potential punctum. The median and standard deviation of pixel intensities is computed for foreground pixels in the neighborhood of each seed point. The size of the local neighborhood is made dynamic in order to maintain sufficient statistics, with a minimum size of 5 μm^2. Seed points with intensities less than 3 standard deviations above the local median are rejected. For seed points that pass this threshold, adjacent pixels that pass a less stringent threshold (the minimum of 2 standard deviations above the median and the average of the median and seed point intensities) are clustered. In order to prevent neighboring puncta from being clustered together, intensities for newly added pixels are required to decrease if adjacent established pixels are already close to the lower threshold. Once the clustering is complete, puncta are smoothed in the same manner as the foreground and rejected if they are smaller than 0.03 μm^2. Pixels that are part of a punctum passing all of the above criteria are removed from the foreground mask so as not to be included in the threshold calculation for future puncta. After every seed point has been tested, those that failed are iterated over again until no new puncta are added. At the beginning of each iteration, puncta smaller the 3 times the minimum size threshold are removed to be reclustered. Synapses are defined as a colocalization of PSD-95 and VGLUT1 puncta. Two puncta are considered colocalized if they have at least 1 pixel of overlap. Synapse densities as well as the densities of presynaptic and postsynaptic markers are calculated using dendrite areas computed by counting pixels within a region of interest belonging to the foreground mask in the MAP2 channel. A similar approach for calculating synapse density has been described previously (Nielend *et al.*, 2014). Synapse size was calculated using the number of pixels representing each colocalization event. Outliers were removed using the ROUT method in GraphPad Prism (version 7.0a) with a Q value equal to 5%.

ELISA

Cortical cultures were grown in 6-well plates (600,000 cells per well). At DIV17-18, all media was removed and replaced with fresh Neurobasal. After 4 h, each well was treated with compound dissolved in DMSO (1:1000) for 24 h. After the treatment period, the media was removed and the cells washed once with ice-cold DPBS. To each well was added 200 µL of Cell Extraction Buffer (Life Technologies) supplemented with cOmplete and PhoSTOP inhibitors, and incubated on ice for 5-10 min. Plates were scrapped and the contents collected. The samples were centrifuged at 10,000 x g for 10 min at 4°C and subjected to a BDNF ELISA assay (ThermoFisher) as per the manufacturer's protocol with the exception that the colorimetric signal was only allowed to develop for 8 minutes.

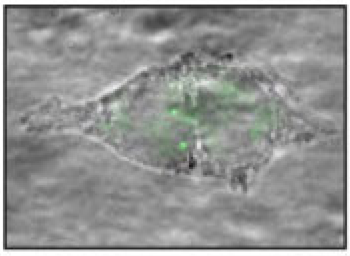
ddPCR

Cortical cultures were grown in 6-well plates (600,000 cells per well) until DIV17-18. At that time, cells were treated with compounds (1:1000 dilution from DMSO stock solutions) for 24h. Cells were then lysed using QIAzol Lysis Reagent (QIAGEN) and RNA extracted using the RNeasy isolation kit (QIAGEN) following instructions of the manufacturer. The resulting RNA was converted to cDNA using the iScript cDNA Synthesis Kit (BioRad). Droplets containing PCR master mix and taqman probes for BDNF (ThermoFisher, RN02531967_s1) and ESD (ThermoFisher, RN01468295_g1) were generated using the QX200 Droplet Digital PCR System (BioRad). Following PCR amplification, BDNF signal was quantified and normalized to the housekeeping gene ESD.

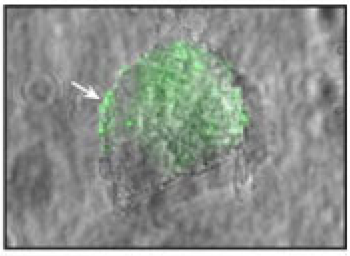
5-HT2A Staining Experiments

Cells were plated at a density of 35,000 cells/well on glass coverslips in 24 well plates. At DIV6 and DIV19, cells were fixed as described for the neuritogenesis experiments (vide supra). Fixative was aspirated and each well washed three times with DPBS. Cells were permeabilized and blocked using 0.1% Triton X-100 (ThermoFisher) and 5% goat serum (Vector Labs S-1000) in DPBS (TPG) for 1 hour at room temperature with gentle shaking. Plates were incubated overnight at 4°C with gentle shaking with anti-MAP2 (1:1000) and rabbit anti-5-HT_{2A} (Millipore Sigma PC176, 1:100) antibodies diluted in TPG. The next day, plates were washed three times for 5 min each with wash buffer (0.1% Triton X-100 in DPBS). Plates were incubated for 1 hour at room temperature in TPG containing secondary antibodies conjugated to Oregon Green 488 (Life Technologies, 1:500) and Alexa Fluor 568 (Life Technologies, 1:500). Plates were again washed three times for 5 min each with wash buffer (0.1% Triton X-100 in DPBS) and post-fixed for 10 min with 4% PFA in DPBS. Cells were washed three times with DPBS and mounted onto microscope slides using Prolong Gold (Life Technologies). After curing for 24 hours at room temperature, images of neurons were collected using a confocal microscope (Olympus FV1000) with a 60x oil objective (1.42 NA).

The anti-5-HT_{2A} antibody used in these studies (i.e., Millipore Sigma PC176) was produced using a peptide antigen corresponding to residues 22-41 of the rat 5-HT_{2A} receptor. The specificity of an antibody produced using the same antigen has been validated previously (Garlow *et al.*, 1993). As it was unclear from the manufacturer's information whether or not the antibody utilized in our studies was produced using the same carrier protein (McDonald and Mascagni, 2007), we performed our own validation experiments. Briefly, HEK293T cells (ATCC, CRL-3216) and 198A2 cells (i.e., a HEK293 cell line stably expressing 5-HT_{2A} receptors, donated by Javier González-Maeso; see González-Maeso *et al.*, 2003; Ebersole *et al.*, 2003) were fixed, stained, and imaged with a 100x oil objective (1.3 NA) on an inverted widefield microscope (Leica DMIL). Representative bright-field images (grayscale) overlaid with fluorescence images (green) indicating 5- HT2A expression are shown below. The cells expressing 5-HT_{2A} receptors exhibit significantly more fluorescence and the expected staining at the cell membrane (white arrow), validating this antibody for immunofluorescence studies.



HEK293T
(Does Not Express 5-HT$_{2A}$)



1988A
(Stably Expresses 5-HT$_{2A}$)

Drosophila Experiments

For morphological analysis, we crossed *221-Gal4* with *UAS-cd4-tdGFP*, collected the progeny at either the first larval instar (early treatment) or late second larval instar (late treatment), then transferred the larvae to grape agar plates smeared with yeast paste. This yeast paste was dissolved in 1 mL of autoclaved water containing 0.1% DMSO with or without compounds dissolved at concentration of 10 µM. Whole, live wandering third instar larvae were mounted in 90% glycerol under coverslips sealed with grease and imaged using an Olympus FV1000 laser scanning confocal microscope. For fly stocks, we used the Gal4 driver line, *221-Gal4* (Grueber *et al*., 2003), to drive the expression of the membrane marker, *UAS-cd4-tdGFP* (Han *et al*., 2011), to visualize dendrite morphology for all conditions. Collected Z-stacks containing the dendritic arbors of the class I da sensory neurons were used for analysis. One neuron from segment A3 or A4 was imaged per larvae and three larvae were imaged per drug condition per treatment window (early vs. late treatment). All larval drug treatments were performed at least three separate times. Total dendrite length and the number of branch points were determined from maximum Z projections of the Z-stack image files using the Simple Neurite Tracer plugin for ImageJ Fiji (Longair *et al*., 2011). Data acquisition and analysis was performed by an experimenter blinded to treatment conditions.

Zebrafish Experiments

Wildtype fish (NHGRI-1) were dechorionated 24 h post fertilization (hpf) and placed individually into a 96-well plate containing chemicals of interest (10 µM compound, 0.1% DMSO). Larvae were raised in a light-cycled incubator (28°C) and subsequently subjected to an activity assay for 16 hours, from 5pm to 9am, at 5.5-6.5 days post fertilization (dpf). Specifically, they were imaged using DanioVision with a light cycle mimicking their natural day/night cycle. Subsequently, fish larvae (6.5 dpf) were immediately fixed following the movement assay using 4% aqueous paraformaldehyde overnight. Head-width measurements were performed by imaging larvae dorsally using a stereomicroscope (12x magnification) and a digital ruler (ImageJ) to measure the distance between the inner edges of each eye. Data acquisition and analysis was performed by an experimenter blinded to treatment conditions.

Golgi-Cox Staining

Female Sprague Dawley rats (~8 weeks old) were given an intraperitoneal injection of DMT, ketamine, or vehicle and sacrificed via decapitation 24 h later. Tissue was prepared following the protocol outlined in the FD Neurotechnologies Rapid GolgiStain Kit (FD Neurotechnologies) with slight modifications. Brains were stored in solution C for 2 months prior to slicing into 120 µm sections using a vibratome. These slices were placed onto microscope slides that were pre-coated with (3-aminopropyl)triethoxysilane. Slices were air dried for a week before staining. Slides were immersed in water twice for 2 minutes, DE solution for 10 minutes, and then water for 2 minutes. After this, slides were immersed sequentially in 25% ethanol for 1 minute, 50% ethanol for 4 minutes, 75% ethanol for 4 minutes, 95% ethanol for 4 minutes, and 100% ethanol for 4 minutes. Slides were then briefly dipped into xylenes before being mounted using DPX Mountant For Histology (Sigma), air-dried, and imaged on a Zeiss AxioScope. Spines were traced in three dimensions using Neurolucida software (version 10) at 100x magnification. Data acquisition and analysis was performed by an experimenter blinded to treatment conditions. Data represents individual neurons taken from 3 different animals per treatment,

Electrophysiology

Female Sprague Dawley rats (~8 weeks old) were given an intraperitoneal injection of DMT or vehicle. After 24 h, rats were anesthetized with isofluorane and transcardially perfused with ice-cold artificial cerebrospinal fluid (ACSF), containing 119 mM NaCl, 26.2 mM $NaHCO_3$, 11 mM glucose, 2.5 mM KCl, 1 mM NaH_2PO_4, 2.5 mM $CaCl_2$ and 1.3 mM $MgSO_4$. Brains were rapidly removed and 300 μm coronal slices from the mPFC were cut on a Leica VT1200 vibratome (Buffalo Grove, IL) with ice-cold ACSF solution. Slices were incubated in 32°C NMDG solution for 10 minutes, transferred to room temperature ACSF, and held for at least 50 minutes before recording. All solutions were vigorously perfused with 95% O_2 and 5% CO_2. Spontaneous excitatory postsynaptic currents (sEPSCs) were recorded at -70 mV in 32°C ACSF. Cells were patched with 3-5 MΩ borosilicate pipettes filled with intracellular solution containing 135 mM cesium methanesulfonate, 8 mM NaCl, 10 mM HEPES, 0.3 mM Na-GTP, 4 mM Mg-ATP, 0.3 mM EGTA, and 5 mM QX-314 (Sigma, St Louis, MO). Series resistance was monitored throughout experiments; cells were discarded if series resistance varied more than 25%. All recordings were obtained with a Multiclamp 700B amplifier (Molecular Devices, Sunnyvale, CA). Analysis was performed with the Mini Analysis program (Synaptosoft, Decatur, GA) with a 4 pA detection threshold. Data represents individual neurons taken from 3 different animals per treatment. Data acquisition and analysis was performed by experimenters blinded to treatment conditions.

Abstract

Psilocybin therapy shows antidepressant potential, but its therapeutic actions are not well understood. We assessed the subacute impact of psilocybin on brain function in two clinical trials of depression. The first was an open-label trial of orally administered psilocybin (10 mg and 25 mg, 7 d apart) in patients with treatment-resistant depression. Functional magnetic resonance imaging (fMRI) was recorded at baseline and 1 d after the 25-mg dose. Beck's depression inventory was the primary outcome measure (MR/J00460X/1). The second trial was a double-blind phase II randomized controlled trial comparing psilocybin therapy with escitalopram. Patients with major depressive disorder received either 2 × 25 mg oral psilocybin, 3 weeks apart, plus 6 weeks of daily placebo ('psilocybin arm') or 2 × 1 mg oral psilocybin, 3 weeks apart, plus 6 weeks of daily escitalopram (10-20 mg) ('escitalopram arm'). fMRI was recorded at baseline and 3 weeks after the second psilocybin dose (NCT03429075). In both trials, the antidepressant response to psilocybin was rapid, sustained and correlated with decreases in fMRI brain network modularity, implying that psilocybin's antidepressant action may depend on a global increase in brain network integration. Network cartography analyses indicated that 5-HT$_{2A}$ receptor-rich higher-order functional networks became more functionally interconnected and flexible after psilocybin treatment. The antidepressant response to escitalopram was milder and no changes in brain network organization were observed. Consistent efficacy-related brain changes, correlating with robust antidepressant effects across two studies, suggest an antidepressant mechanism for psilocybin therapy: global increases in brain network integration.

Main

Depression is a highly prevalent mental health condition[1], the incidence of which has increased during the COVID-19 pandemic[2], for example, as reflected in increased prescriptions of antidepressant medications[3]. However, even the best-performing antidepressant drugs show modest efficacy, non-negligible side effects, discontinuation problems and high relapse rates[4-7], highlighting the need for new, improved treatments[8].

Patients with a diagnosis of depression often exhibit a negative cognitive bias, characterized by pessimism, poor cognitive flexibility, rigid thought patterns and negative fixations regarding 'self' and the future[9,10]. A number of authors have directly or indirectly taken inspiration from dynamical systems theory to describe depressive episodes as 'attractor states' (stereotyped cognitive states with 'gravitational pull'[11]).

Neuroimaging research has consistently found examples of abnormal brain functioning in depression, resonant with its phenomenology[12-14]. A hierarchically supraordinate intrinsic brain network[15], the default mode network (DMN), is associated with introspection and self-referential thinking[16]. These cognitive functions are often overactive in depression[9], and several studies have linked excessive engagement of DMN functioning with depressive symptomatology[12].

In addition to the DMN, other higher-order brain networks such as the executive network (EN) and salience network (SN) have been implicated in depression[14,17]. These networks are associated with 'cognitive control' and internal versus external attention switching[18-20]. Such attentional switching is often impaired in depression[21]. Tellingly, the serotonin 2A (5-HT$_{2A}$) receptor subtype, which is the key proteomic binding site of 'classic' serotonergic psychedelic drugs, such as psilocybin[22], is most densely expressed in a broad pattern of cortex that closely resembles a conjunction map of the DMN, EN and SN[23], corresponding to the transmodal portion of the brain's principal hierarchical gradient[15].

In the last 15 years, at least six separate clinical trials have reported impressive improvements in depressive symptoms with psilocybin therapy[24]. Included among these studies are (1) an open-label trial in treatment-resistant depression[25] and (2) a double-blind, randomized controlled trial (DB-RCT) with an active comparator, the selective serotonin reuptake inhibitor (SSRI) and conventional antidepressant, escitalopram[26]. These two trials, which included pre-treatment and post-treatment fMRI, are the focus of this paper's analyses.

The therapeutic action of psilocybin and related psychedelics is incompletely understood; however, one model proposes that psychedelics cause a 5-HT$_{2A}$ receptor-induced dysregulation of spontaneous population-level neuronal activity, linked to a temporary 'disintegration' of intrinsic functional brain networks[27] and a hypothesized decrease in the precision-weighting of predictive models encoded (at least in part) by the integrity of functional modules[28]. One important corollary of modular 'disintegration' seems to be the broadening of the brain's functional repertoire of states, commensurate with a broader or flatter global energy landscape[29].

Here we hypothesize that the well-replicated finding of brain network disintegration and desegregation under psychedelics[30,31] will be apparent subacutely, in post-treatment resting-state fMRI data. We also hypothesize that this effect, consistent with a flatter energy landscape, will relate to improved depression outcomes and will not be observed after a course of the SSRI, escitalopram.

Results

Open-label trial

Rapid antidepressant effect of psilocybin therapy

Patients with treatment-resistant depression (TRD) participated in a single-arm, open-label psilocybin therapy clinical trial (Fig. 1a). Baseline clinical assessment and resting-state fMRI were followed by fixed-order 'low' (10mg) and 'high' (25mg) psilocybin therapy dosing days (DDs) that were separated by 1 week. A second clinical assessment and fMRI scan were conducted 1d after DD2. Remote assessments of clinical status were conducted 1 week, 3 months and 6 months after DD2. Further details are available in Methods and elsewhere[25].

Of the 19 patients recruited, 3 were excluded due to excessive fMRI head motion (Fig. 2a). We first confirmed an antidepressant effect of psilocybin in this imaging sample of 16 patients (mean age, 42.75 years, s.d.=10.15, 4 females) using the Beck Depression Inventory (BDI-1A). This patient-rated measure was preregistered for the original investigation (gtr.ukri.org MR/J00460X/1). The BDI captures a broad range of symptoms and places particular emphasis on the cognitive features of depression[32], which may be an important target of psilocybin therapy.

Baseline BDI scores indicated severe depression (mean BDI=34.81, s.d.=7.38). In line with our previous report[25], rapid, substantial and sustained reductions in depression severity were observed after treatment (Fig. 3a,b). Relative to baseline, significant BDI reductions were observed at 1 week (mean difference, -21.0 points t_{15}=7.11, 95% confidence interval (CI) -27.30 to -14.71, $P<0.001$, Cohen's d=1.78) and still evident at 6 months (mean difference, -14.19 points t_{15}=4.26, 95% CI -21.29 to -7.09, $P<0.001$, d=1.07).

Decreased brain modularity one day after psilocybin therapy

To test our primary hypothesis, preprocessed fMRI data were used to estimate normalized network modularity from Pearson correlation functional connectivity matrices of the cortex (Methods). Confirming our primary hypothesis, brain network modularity was significantly reduced (Fig. 4a) 1d after psilocybin therapy (mean difference, -0.29; t_{15}=2.87, 95% CI 0.07 to 0.50, P=0.012, d=0.72). This result implies a global increase in functional connectivity between the brain's main intrinsic networks.

Fig. 1 - **Trial design schematics. a**, Open-label trial. Eligible patients attended a baseline clinical assessment and resting-state fMRI visit. This was followed by two orally administered psilocybin therapy DDs separated by 1 week, which differed in dose strength (10 mg on DD1, 25 mg on DD2). The post-treatment fMRI scan occurred 1 d after DD2. Remote clinical assessment continued for 6 months. **b**, DB-RCT. Patients attended a baseline clinical assessment and resting-state fMRI visit and were randomly assigned to the psilocybin arm (top) or escitalopram arm (bottom). The psilocybin arm involved 2 × 25 mg psilocybin therapy DDs with 3 weeks of daily placebo capsules following each DD. The escitalopram arm involved 2 × 1 mg psilocybin therapy DDs with 3 weeks of 10 mg daily escitalopram following DD1 and 20 mg of escitalopram following DD2. Both groups attended a post-treatment clinical assessment and fMRI visit 3 weeks and 1 d after DD2.

Decreased modularity predicts improved clinical outcomes

We hypothesized that decreased brain network modularity would relate to the sustained improvements in depression severity that follow psilocybin therapy. To test this, we calculated Pearson correlations between the post-treatment brain modularity and BDI scores from the three post-treatment time points (1 week, 3 months, 6 months). After false discovery rate (FDR) correction for multiple comparisons, a strong significant Pearson correlation was observed at the 6 months primary end point (r_{14}=0.64, 95% CI 0.29 to 0.84, P=0.023; Fig. 4b). Directionally consistent relationships were seen at 3 months (r_{14}=0.46, 95% CI 0.03 to 0.74, P=0.114) and 1 week (r_{14}=0.29, 95% CI -0.16 to 0.64, P=0.284), but these did not survive correction. Pre-treatment versus post-treatment changes in modularity significantly correlated with change in BDI score at 6 months, relative to baseline (r_{14}=0.54, 95% CI 0.14 to 0.78, P=0.033; Fig. 4c). These results imply that decreased brain modularity 1d after psilocybin therapy relates to long-term improvements in depression symptom severity.

DMN changes in within-network and between-network functional connectivity one day after treatment

Previous research has implicated depressive symptomology with hyperconnectivity of the DMN[12] and hypoconnectivity of the DMN with other higher-order 'cognitive' networks, including the EN and SN[14,17]. We therefore tested for evidence of these abnormalities being attenuated after treatment using functional cartography (Methods). Consistent with our previous hypothesis, significant reductions in DMN network recruitment (mean difference, -0.54; t_{15}=-2.99, 95% CI -0.92 to -0.15, P=0.009, d=0.75; Fig. 4d) and increased between-network integration between the DMN and EN (mean difference, 0.53 t_{15}=3.01, 95% CI 0.15 to 0.90, P=0.01, d=0.75) and between the DMN and SN (mean difference, 0.55 t_{15}=2.89, 95% CI 0.14 to 0.95, P=0.01, d=0.72; FDR-corrected) were observed 1d after psilocybin therapy. An exploratory analysis of the changes in network recruitment and between-network integration of other brain networks is available in Supplementary Fig. 2.

Double-blind randomized controlled trial

Psilocybin therapy versus escitalopram for depression

The design of this DB-RCT (Fig. 1b) gave a new opportunity to compare not just the safety and efficacy, but also the mechanisms of action of psilocybin therapy to those of a conventional antidepressant drug, escitalopram. Patients with major depressive disorder (MDD) were randomly allocated to a 'psilocybin arm' or 'escitalopram arm' (Fig. 1b). Baseline clinical assessment and resting-state fMRI was followed by DD1, when patients received either 25mg psilocybin (psilocybin arm) or a presumed inactive 1mg psilocybin dose (escitalopram arm). All patients were informed that they would receive psilocybin but were blind to the dosage. DD2 occurred 3 weeks after DD1 and was a duplicate dosage. Beginning 1d after DD1, patients took daily capsules for 6 weeks and 1d in total. For both conditions, one capsule per day was ingested for the first 3 weeks and two capsules per day were ingested thereafter. Capsule content was either inert placebo (microcrystalline cellulose in the psilocybin arm) or 10mg escitalopram in the escitalopram arm (10mg daily for the first 3 weeks and 2×10mg (20mg) daily for the final 22d). Further details are available in Methods and elsewhere[26].

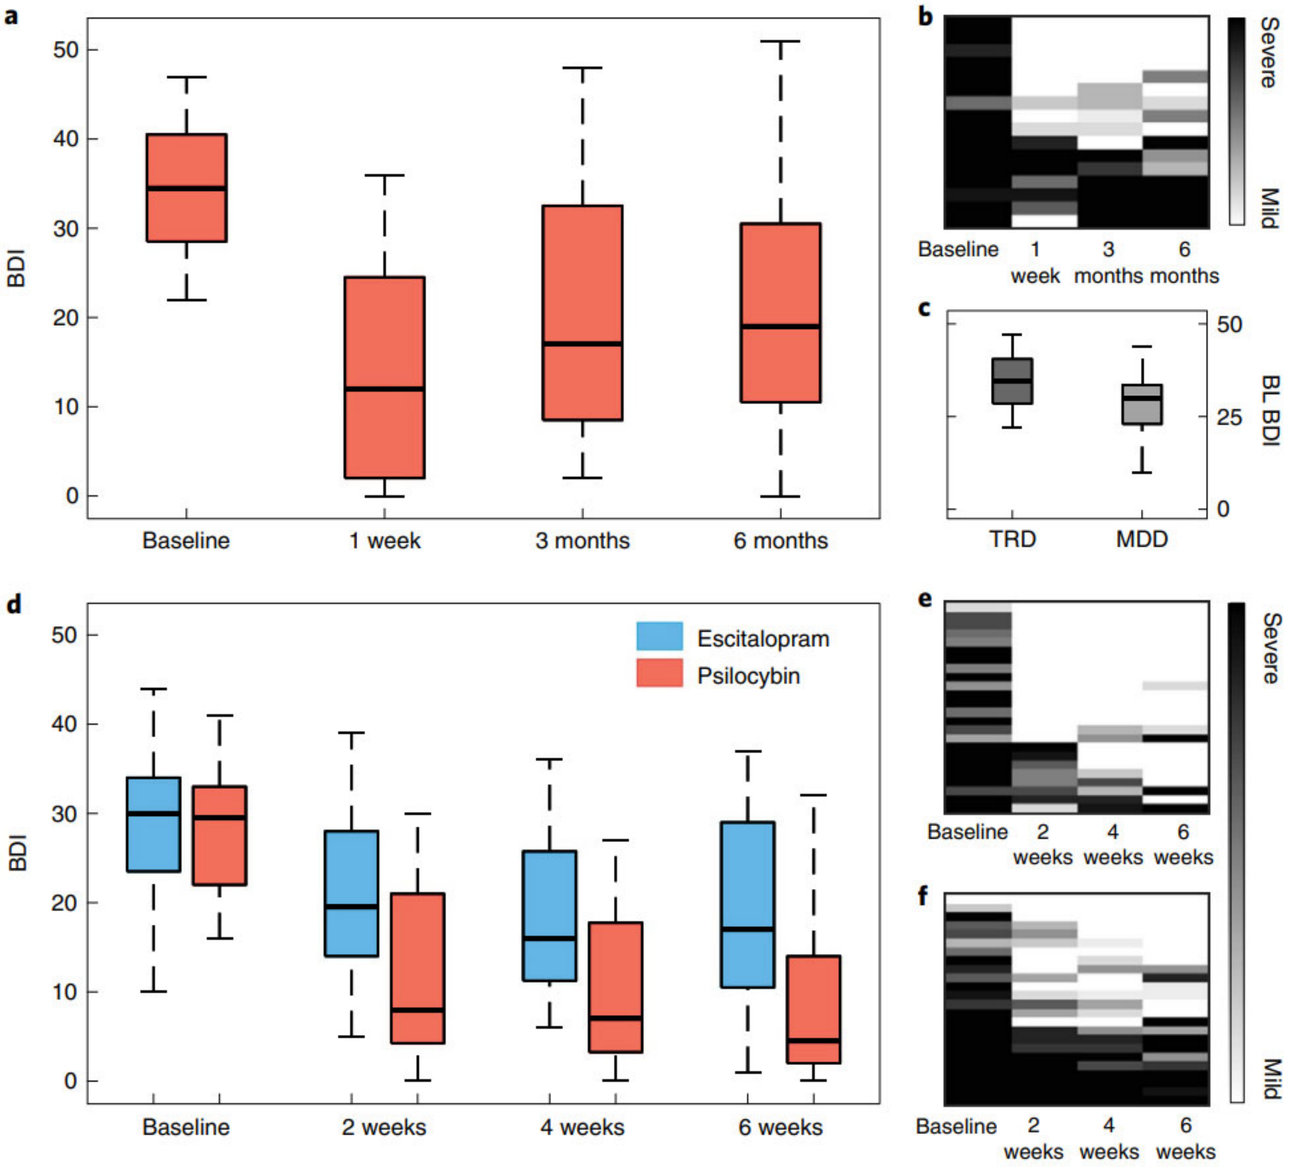

Fig. 3 - **Beck depression inventory scores.** **a**, Open-label trial box plots of BDI scores of patients with TRD across time points. **b**, Qualitative raster plots of individual patient's BDI score for each time point (columns). **c**, Baseline BDI of patients with TRD in the open-label trial was significantly greater than that in patients with MDD in the DB-RCT (t_{57}= 3.01, 95% CI 2.18 to 10.88, P= 0.013, d= 0.83). **d**, DB-RCT BDI scores from each study arm and time point. **e**,**f**, Qualitative raster plots of individual patient's BDI for each time point for the psilocybin arm (**e**) and escitalopram arm (**f**). The box plot central marks represent the group median, the box edges represent the 25th to 75th percentiles and the whiskers extend to the data range. Independent samples of n= 16 TRD were used in **a** and alongside n= 43 MDD in **c**, of which n= 21 in the escitalopram arm and n= 22 in the psilocybin arm are displayed in **d**. The rows from each qualitative raster plot were ordered by the sum BDI score across time points.

Of the 59 patients with MDD recruited, 29 were randomly allocated to the escitalopram arm. Of those, four discontinued due to adverse reactions to escitalopram, one was lost due to the COVID19 UK lockdown and three were excluded due to excessive fMRI head motion (Fig. 2b). The remaining 21 patients (mean age, 40.9 years, s.d.=10.1, 6 female) were included in the escitalopram imaging sample. Thirty patients were randomly allocated to the psilocybin arm. Of those, one was excluded for choosing not to take the daily (placebo) capsules, two did not attend the post-treatment session due to the COVID-19 UK lockdown and five were excluded due to excessive fMRI head motion. The remaining 22 patients (mean age, 44.5 years, s.d.=11.0, 8 female) were included in the psilocybin imaging sample (Fig. 2b).

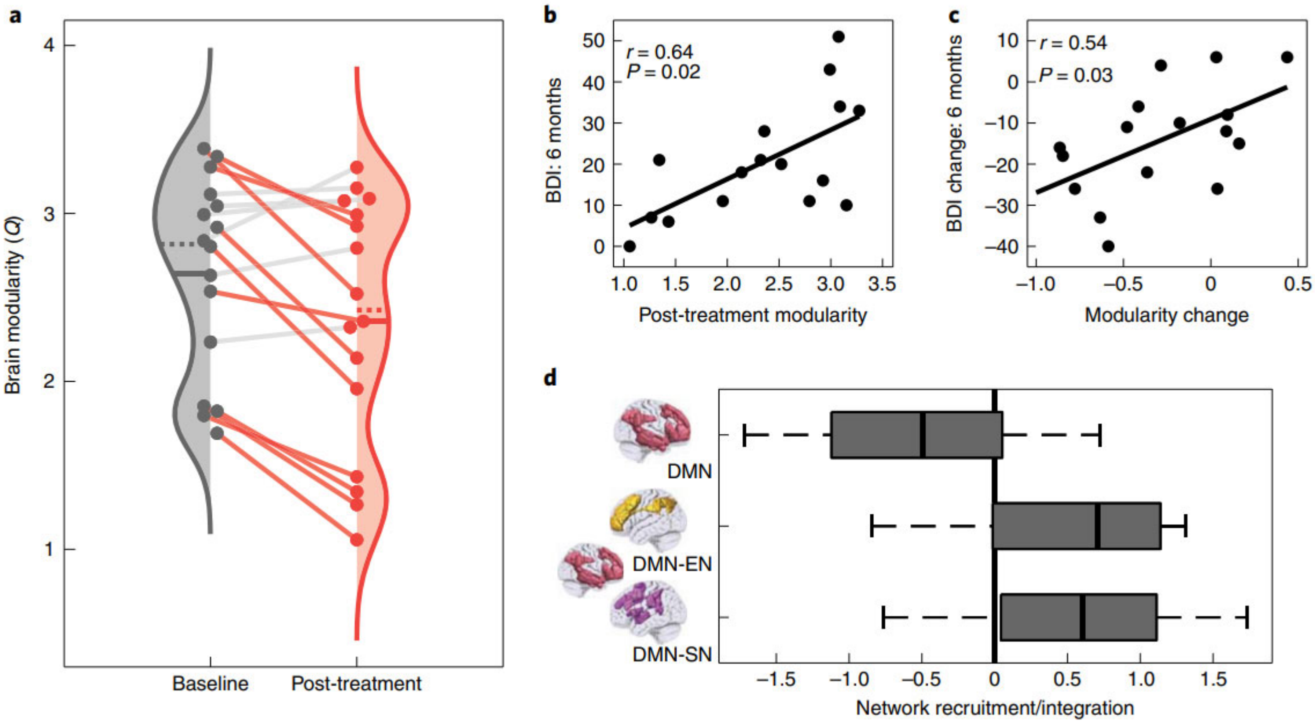

Fig. 4 - Responses of patients with TRD to psilocybin therapy relate to increases in brain network integration. a, Brain modularity (normalized Q) significantly reduced, indicating a global increase in brain network integration following psilocybin therapy in patients with TRD (t_{15}= 2.87, 95% CI 0.07 to 0.50, P= 0.012, d= 0.72). The solid and dotted lines represent the mean and median, respectively. Patient's data are connected by solid lines and rendered in color if modularity decreased. **b**, Absolute post-treatment scan modularity correlated with absolute BDI scores at the 6 months primary end point (r_{14}= 0.64, 95% CI 0.29 to 0.84, P= 0.023, FDR-corrected). **c**, Post-treatment change in brain modularity significantly correlated with treatment response (BDI, baseline - 6 months) (r_{14}= 0.54, 95% CI 0.14 to 0.78, P= 0.033). **d**, DMN (red) recruitment decreased (t_{15}=-2.99, 95% CI -0.92 to -0.15, P= 0.009, d= 0.75) and its between-network integration with the EN (gold) (t_{15}= 3.01, 95% CI 0.15 to 0.90, P= 0.01, d= 0.75) and SN (purple) (t_{15}= 2.89, 95% CI 0.14 to 0.95, P= 0.01, d= 0.72) increased following psilocybin therapy (all FDR-corrected). The box plot central marks represent the group median, the box edges represent the 25th to 75th percentiles and the whiskers extend to the data range. Independent samples of n= 16 TRD were used in **a-d**.

The BDI was a primary outcome measure for the open-label trial (MR/J00440/1) and a secondary outcome measure for this DB-RCT (ClinicalTrials.gov identifier NCT03429075); however, this measure proved to be an especially sensitive index of post-psilocybin reductions in symptom severity across the trials[26]. Between trials, baseline BDI (Fig. 3c) was significantly greater in the open-label TRD trial compared with the DB-RCT MDD trial (mean difference, 6.53 points t_{57} = 3.01, 95% CI 2.18 to 10.88, P = .013, d = 0.83). This difference is likely due to TRD being an inclusion criteria in the open-label trial, but not in this DB-RCT.

As described in our previous report[26], BDI-measured reductions in depressive symptom severity were significantly greater after psilocybin than escitalopram, indicating superior efficacy of psilocybin therapy versus escitalopram (Fig. 3d). Moreover, we confirmed the statistical significance of this contrast within the smaller neuroimaging sample included in the present analyses after testing for an arm × time point analysis of variance interaction on BDI scores ($F_{3,123}$, 4.47; P=0.005). FDR-corrected pairwise comparisons relative to baseline were significantly different at 2 weeks (mean difference, -8.73; t_{41}=-3.66, 95% CI -13.55 to -3.91, P=0.002, d=0.98), 4 weeks (mean difference, -7.79 t_{41}=-2.69, 95% CI -13.62 to -1.95, P=0.013, d=0.77) and at 6 weeks (mean difference, -8.78 t_{41}=-2.61, 95% CI=-15.58 to -1.97, P=0.013, d=0.75), all favoring the psilocybin arm.

Decreased brain modularity for psilocybin but not escitalopram

Reconfirming our primary hypothesis (Fig. 5a,b) and replicating analyses on the open-label trial data, brain network modularity was significantly reduced at the trial's primary end point, 3 weeks after psilocybin therapy (mean difference, -0.39; t_{21}=-2.20, 95% CI -0.75 to -0.02, P=0.039, d=0.47). Moreover, for the psilocybin condition, post-treatment decreases in brain network modularity significantly correlated with improvements in depression symptom severity at this primary end point (r_{20}=0.42, P=0.025, one-tailed).

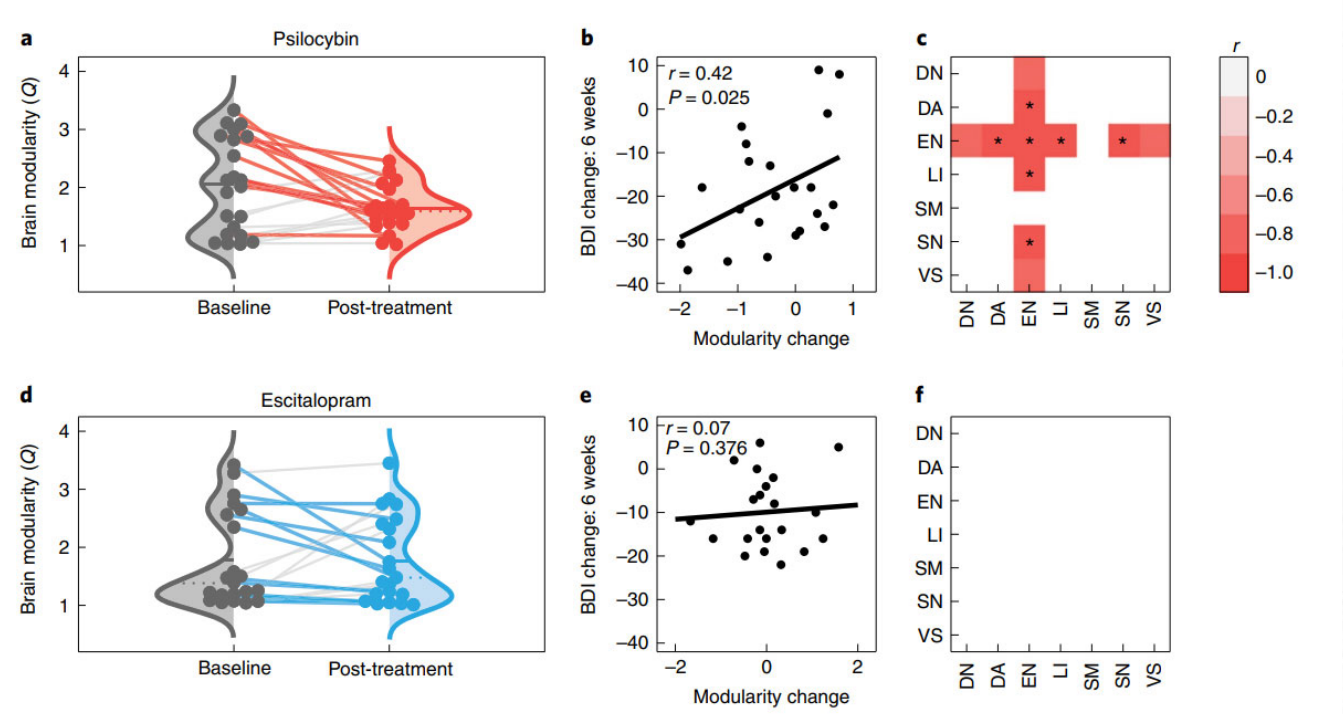

Fig. 5 - Increased global brain network integration correlates with treatment response following psilocybin, but not following escitalopram. a, Significant decreases in brain network modularity (normalized Q), indicating greater brain network integration following psilocybin therapy (t_{21}=-2.20, 95% CI -0.75 to -0.02, P= 0.039, d= 0.47). The solid and dotted lines on the distributions represent the mean and median, respectively. Individual patient data are represented and connected with solid lines between sessions that are rendered with color if modularity decreased between sessions. **b**, Post-treatment change in brain modularity significantly correlated with the treatment response primary end point (BDI, baseline - 6 weeks) (r_{20}= 0.42, P= 0.025, one-tailed). **c**, Significant correlations between increased dynamic network flexibility and the psilocybin primary end point treatment response (BDI, baseline - 6 weeks) are colored (white, P> 0.05; *survives FDR correction). The EN exhibited the largest correlation (r_{20}=-0.76, 95% CI -0.90 to -0.50, P= 0.001). **d-f**, The equivalent analyses of brain network modularity in the escitalopram arm did not show significant session differences (**d**), relationship to individual treatment response (**e**) or network flexibility (**f**). n= 22 independent psilocybin arm samples are displayed in **a-c** and n= 21 independent escitalopram arm samples are displayed in **d-f**. DN, default mode network; DA, dorsal attention; EN, executive network; LI, limbic; SM, somatomotor; SN, salience network; VS, visual.

Notably, there was no significant interaction between treatment arm and scanning session on network modularity ($F_{1,41}$=2.719, P=0.107); however, there was evidence that the reduction in network modularity and its relationship to depression severity may be specific to the psilocybin arm. Namely, in the escitalopram group (Fig. 5d,e), network modularity did not change from baseline (mean difference, 0.01; t_{20}=0.07, 95% CI -0.35 to 0.33, P=0.95, d=0.02) and there was no significant correlation between changes in modularity and changes in BDI scores (r_{19}=0.08; P=0.361, one-tailed).

Response to psilocybin correlates with network flexibility

The specific changes in network recruitment observed 1 d after psilocybin therapy in the open-label trial were not replicated at 3 weeks in this DB-RCT (Supplementary Information). However, the faster fMRI scanning protocol adopted in the DB-RCT generated twice as much temporal data per scanning session (Methods). This provided the rare opportunity to examine changes in the dynamic flexibility of brain networks following psilocybin therapy.

The metric known as 'dynamic flexibility' indexes how often brain regions change their community allegiance over time, during the course of an fMRI scan[33,34] (Methods). Reduced functional dynamics have been previously associated with depression symptomology[14]. In an exploratory analysis, post-psilocybin therapy changes in network flexibility were correlated with changes in BDI score (Fig. 5c). After FDR correction, increased EN dynamic flexibility strongly correlated with greater symptom improvement at the 6-week primary end point for the psilocybin arm (r_{20}=-0.76, 95% CI -0.90 to -0.50, P=0.001). Strong correlations that survived FDR correction were also observed when combining regions from the EN with other lateral frontoparietal networks, such as the SN and dorsal attention network (Fig. 5c). Critically, there were no significant correlations between changes in BDI scores and changes in dynamic flexibility in the escitalopram arm (Fig. 5f).

Discussion

In light of growing evidence for the antidepressant efficacy of psilocybin therapy[26], the present findings advance our understanding of its possible underlying brain mechanisms. Across two trials, decreased brain modularity was observed and correlated with improvements in depressive symptomatology. Moreover, this antidepressant action may be specific to psilocybin therapy, as no changes in modularity were observed with the conventional SSRI antidepressant, escitalopram.

Research into the acute brain action of psychedelics has revealed well-replicated changes in global brain function that are somewhat consistent with those observed here (an increased repertoire of inter-regional and between-network functional connectivity (FC)[29-31]). A previous analysis of ours had suggested some contrasting changes in the architecture of spontaneous brain function 1d following psilocybin treatment for depression relative to what has been observed during the acute psychedelic state itself: spatially expanded DMN FC (1d after treatment for TRD) versus acute DMN 'disintegration'[25]. However, others have reported evidence of increased inter-network FC 1 week and 1 month after psilocybin treatment[35], as well as 1d after ayahuasca, including increases in DMN-SN FC in healthy volunteers[36]. These findings are consistent with the present study, but here we show robust and reliable evidence that increases to global brain network integration accompanies the antidepressant efficacy of psilocybin therapy

The present modularity metrics may be more sensitive indices of the antidepressant action of psilocybin than previously applied time-averaged within-network and between-network FC analyses[25]. Indeed, they may bear relevance to other FC metrics applied to acute-state psychedelic fMRI data[29,30] where a general picture of increased global FC and a broadened dynamic state space has emerged[28]. In this context, the results could be understood as a 'carryover' effect resembling brain dynamics associated with the acute action of psychedelics, albeit at an attenuated level and in a specific population (depressed patients). To show robustness to analytical method, we also carried out more traditional mass-univariate analyses and these yielded consistent findings (Supplementary Figs. 3 and 4). However, an advantage of network modularity is its capacity to elegantly summarize global changes in the brain's functional network organization[37].

Previous research on resting-state activity in depression has found heightened network modularity correlating with symptom severity[17,38]. Additional work implies heightened within-DMN FC and elevated FC between limbic regions such as the amygdala, and high-level cortical regions correlates with ruminative symptoms in depression[12,39]. Taken together, a model emerges of abnormally modular spontaneous brain function in depression that is effectively remediated by psilocybin therapy. According to various findings, the FC energy landscape or state space in depression can be described as abnormally constricted, paralleling the narrow, internally focused, ruminative quality of mood and cognition in the disorder[11]. In contrast, psilocybin seems to increase the brain's ability to visit a broader state space, both acutely and after psilocybin therapy in patients who are depressed, as shown here. Moreover, this 'liberating' action of psilocybin is paralleled by subjective reports of 'emotional release'[40,41] as well as subacute increases in behavioral optimism[9], cognitive flexibility[42] and psychological flexibility after taking a psychedelic drug[43]. Indeed, heightened emotional responsiveness may be specific to psilocybin therapy versus SSRIs[26].

It is plausible that this putative liberating effect of psilocybin on cortical activity occurs via its direct agonist action on cortical 5-HT$_{2A}$ receptors, dysregulating activity in regions rich in their expression. We surmise that chronic escitalopram does not have the same effect on brain modularity due to its more generalized action on the serotonin system and predominant action on inhibitory postsynaptic 5-HT^{1}A receptors, which are richly expressed in limbic circuitry[27,44].

Beyond the global decrease in network modularity after psilocybin, we observed functional changes in DMN, EN and SN dynamics that are consistent with neurobiological models of depression[45]. These high-order transmodal networks house the highest density of 5-HT$_{2A}$ receptors, the principal action site for serotonergic psychedelics[22,23]. Higher-order networks are implicated in the acute action of psychedelics, where they show reduced modularity and increased communication with regions ordinarily outside of their community limits[29-31].

The EN and SN have been associated with tasks requiring cognitive flexibility such as learning and task switching[18,19,46,47]; impaired functioning of these networks have been reported in depression[14,17] and other disorders exhibiting cognitive inflexibility such as autism spectrum disorder[48] and obsessive-compulsive disorder[49]. Our results suggest that decreased modularity or increased flexibility of these networks following psilocybin therapy is a key component of its therapeutic mechanism of action. We did not formally assess cognitive flexibility in the clinical trials reported here but we did observe improvements in general cognitive functioning after psilocybin treatment in the DB-RCT, as well as treatment-specific improvements in 'emotional avoidance' (an inversion of the related construct 'psychological flexibility'[26]).

It should be noted that psychological processes that do not reliably relate to brain modularity changes may have played a role in the main clinical outcomes of this study, and an inability to discount such factors precludes the making of confident inferences that drug alone was the main causal determinant of the imaging outcomes or, indeed, that decreased modularity is sufficient for response to psilocybin therapy. Nevertheless, the changes observed in the neuroimaging data were consistent with previous brain imaging research regarding the acute action of psychedelics and are plausible in light of evidence of elevated modularity and abnormal functioning of higher-order networks in depression[12,17,38,39,50].

Successful phase III DB-RCTs will be required to achieve licensing for psilocybin therapy, but pragmatic trials may better address questions regarding treatment practicability, specificity and optimization[51]. Given the emerging research into psychedelic therapy, it is important for large-scale trials to establish the generalizability, reliability and specificity of psilocybin's antidepressant response. For example, it is likely that efficacy will depend on symptom severity, depression subtypes and comorbidities, as well as other key pharmacological and extrapharmacological factors[52]. For brain imaging studies, we would recommend network modularity analyses such as those employed here. fMRI datasets are complex, burdensome and susceptible to noise, contributing to the challenge of detecting reliable biomarkers. Simplifying composite measures, such as network modularity, combined with a research domain, symptoms-based approach to psychological phenomena, may be a particularly productive way forward[37,51].

It should be noted that the present study's findings do not support baseline modularity as a predictor of response to psilocybin therapy. Patients with a range of baseline modularity values showed modularity reductions after treatment with psilocybin; however, the present results do suggest that the early-phase modularity change is predictive of the long-term treatment response to psilocybin therapy.

It is noteworthy to consider the potentially confounding effects of head motion when interpreting fMRI data. Here, a robust fMRI preprocessing pipeline was employed alongside strict head motion criteria for patient inclusion. To examine robustness to motion, an analysis of head motion was conducted and is available in the Supplementary Information. These analyses bolster the present findings, as there was no evidence that head motion differed between sessions or treatment arms or that it correlated with network modularity. The fMRI data were collected with an eyes-closed protocol, which has some advantages; however, it would be compelling if these findings were replicated in data acquired with an eyes-open protocol. In-scanner sleep can be more likely during eyes-closed fMRI, which is a particular disadvantage[53]. In-scanner sleep cannot be ruled out here. However, the head motion analyses make it unlikely that sleep was a confounding factor. Furthermore, a self-reported visual analog scale of time spent asleep and 'sleepiness' were acquired immediately after all scan runs in study 2. An analysis of these data is available in the Supplementary Information. Critically, ratings of in-scanner sleep or sleepiness were low and did not differ between treatment arms or scanning session.

This study's primary hypothesis was confirmed and replicated despite substantial differences between the design of the two trials. Baseline depression severity was significantly greater in the open-label trial. Furthermore, the open-label trial post-treatment fMRI scan was only 1d after DD2 and was recorded with a 12-channel head coil and a 2-s repetition time (TR). In contrast, the DB-RCT post-treatment scan was conducted 3 weeks after DD2 and was recorded with a 32-channel head coil and a 1.25-s TR.

Acknowledging these differences between the trial designs serves to strengthen the validity of the main findings, as they were robustly replicated; however, the lack of replication in the finer-grained cartography analyses limits the network-specific inferences. A supplementary analysis (Supplementary Information) did confirm that baseline depression severity correlated with within-DMN connectivity and between-network DMN-EN and DMN-SN connectivity, as has been previously reported[12,17,38,39,50]; however, in the DB-RCT, we did not replicate the entirety of the changes in network cartography that were observed in the open-label trial. Given that the observed network effects directly follow predictions from the depression literature, it may be that they are more pronounced in more severe cases, such as those included in the open-label TRD trial. Alternatively, it may be that these effects are only detectable in a short-term, subacute phase after psilocybin therapy and not, for example, 3 weeks later. Parsing the relative contribution of baseline severity and time since treatment will be an important feature of future clinical trials with neuroimaging, ideally with larger samples and repeated scanning sessions.

Dynamic analyses can be challenging to conduct. To be sufficiently powered, time series need to be of sufficient length to be split into multiple time windows that are themselves sufficiently long to compute reliable FC measures, and previous research guided our selection of parameters[54,55]. Collecting sufficient fMRI data in patient cohorts can be challenging, but given the appeal of dynamic analyses, efforts are underway to facilitate and improve them[54]. It should be noted that a sufficiently broad window of time was used to estimate Pearson correlation FC; however, ongoing work is required to better understand how to capture the most functionally meaningful dynamic data.

With these caveats entered, it should be emphasized that the inferences from both cartography analyses converged on the brain's higher-order networks. In particular, the DB-RCT analyses showed robust correlations (r~0.8) between increased higher-order network flexibility and psilocybin's treatment response, and this converges with the open-label trial as well as previous research[14].

In summary, depression is a major public health problem associated with huge burden and cost. Here, we identify a robust, reliable and potentially specific biomarker of response to psilocybin therapy for depression. Our results may help to explain why psilocybin therapy holds promise as a new treatment option in psychiatry.

Methods

Trial overviews

The trial designs (Fig. 1) and main clinical outcomes of the open-label[31] (gtr.ukri.org: MR/J00460X/1) and DB-RCT[32] (clinicaltrials.gov: NCT03429075) trials have been previously published. Both trials were conducted at the National Institute for Health Research Imperial Clinical Research Facility and received Imperial College London Sponsorship, NHS research and Imperial college Joint Research and Compliance Office ethical approval, Health Research Authority and Medicines and Healthcare products Regulatory Agency approval. This work was conducted under a UK Home Office Schedule 1 Drug Licence. All participants provided written informed consent. Participants were not financially compensated.

Participants

For both trials, eligibility required a general practitioner-confirmed diagnosis of unipolar MDD (16+on the 21-item Hamilton Depression Rating scale). The open-label trial had the additional criteria of TRD, as defined by no improvement despite multiple courses of antidepressant medication (mean n=4.6±2.6 past medications; range, 2-11)[39]. Patients were asked whether they had previous experience of using psychedelics. In the open-label trial, 25% had previous experience. Similarly, in the DB-RCT, 31% of patients in the psilocybin arm and 24% in the escitalopram arm had previous experience.

Exclusion criteria were immediate family or personal history of psychosis, risky physical health condition (physician-assessed), history of serious suicide attempts, positive pregnancy test and MRI contraindications. The DB-RCT had the additional exclusion criteria of SSRI contraindications or previous escitalopram use. Of note, treatment resistance was neither an inclusion or exclusion criterion in the DB-RCT. All eligible patients undertook telephone screening interviews, provided written informed consent and their mental and physical medical histories were thoroughly evaluated.

Interventions

Nineteen patients with TRD were recruited to the open-label trial and attended a 1-d pre-treatment baseline session that included eyes-closed resting-state fMRI and clinical assessment (Fig. 1a). This was followed by two psilocybin therapy DDs, separated by 1 week. A low dose of psilocybin (10mg) was orally ingested on DD1 and followed by a high dose (25mg) on DD2. The follow-up fMRI and clinical assessment occurred 1d after DD2. Patients attended an on-site clinical assessment at 1 week after DD2 and completed further clinical assessment electronically at 3 and 6 months. Of the 19 patients with TRD, 16 were retained (mean age, 42.75 years; s.d.=10.15, 4 female) for the present analysis after 3 were excluded due to excessive fMRI head motion (Fig. 2a).

Of the 59 MDD patients recruited to the DB-RCT, a random number generator allocated 30 to the psilocybin arm and 29 to the escitalopram arm (Fig. 1b). The final imaging samples for this investigation were n=22 for the psilocybin arm (mean age, 44.5 years, s.d.=11.0, 8 female) and n=21 for the escitalopram arm (mean age, 40.9 years, s.d.=10.1, 6 female) (Fig. 2b). Patients attended a pretreatment baseline eyes-closed resting-state fMRI. DD1 consisted of either 25mg psilocybin (psilocybin arm) or a presumed negligible 1mg psilocybin (escitalopram arm) dose. All patients were informed that they would receive psilocybin but were blind to the dosage. DD2 occurred 3 weeks after DD1 and was a duplicate dosage. There was no dosage crossover. Beginning 1d after DD1, patients took daily capsules for 6 weeks and 1d in total. For both conditions, one capsule per day was ingested for the first 3 weeks and two thereafter. Capsule content was either inert placebo (microcrystalline cellulose in the psilocybin arm) or escitalopram in the escitalopram arm, 10mg for the first 3 weeks and 2×10mg (20mg) total thereafter.

Measuring depression severity

BDI-1A scores were used to assess depression severity in both studies. This patient-rated measure captures a broader range of symptoms, with an additional focus on the cognitive features of depression, compared with other measures such as the QIDS-SR-16 (ref. [40]). BDI was preregistered as a primary outcome measure in the open-label trial (gtr.ukri.org MR/J00460X/1) and was measured at baseline and 1 week, 3 months and 6 months after DD2. For the DB-RCT, BDI was measured at baseline and 2, 4 and 6 weeks after DD1. BDI was a secondary outcome measure for this DB-RCT (ClinicalTrials.gov NCT03429075) and was used here to test for a replication of the effects observed in the open-label trial.

MRI acquisition

Brain imaging was performed on a 3T Siemens Tim Trio at Invicro. Anatomical images were acquired using the Alzheimer's Disease Neuroimaging Initiative, Grand Opportunity (ADNI-GO[56]) recommended MPRAGE parameters (1-mm isotropic voxels; TR, 2,300ms; TE, 2.98ms; 160 sagittal slices; 256×256 in-plane field of view; flip angle, 9 degrees; bandwidth, 240Hz per pixel; GRAPPA acceleration, 2).

In both studies, eyes-closed resting-state fMRI data were collected with T2*-weighted echo-planar images with 3-mm isotropic voxels. In study 1, a 12-channel head coil was used to acquire 240 volumes in ~8min: TR, 2,000ms; TE, 31ms; 36 axial slices; flip angle, 80 degrees; bandwidth, 2,298Hz per pixel; and GRAPPA acceleration, 2). In study 2, a 32-channel head coil was used to acquire 480 volumes in ~10min: TR, 1,250ms; TE, 30ms; 44 axial slices; flip angle, 70 degrees; bandwidth, 2,232Hz per pixel; and GRAPPA acceleration, 2).

fMRI data preprocessing

Imaging data were preprocessed via a custom in-house pipeline composed of tools from the FMRIB Software Library[57], Analysis of Functional NeuroImages (AFNI)[58], Freesurfer[59] and Advanced Normalization Tools[60] packages. Patients were excluded if either fMRI scan contained >20% of volumes with a framewise displacement >0.5mm.

Specifically, the following preprocessing stages were performed: (1) removal of the first three volumes; (2) despiking (3dDespike, AFNI); (3) slice time correction (3dTshift, AFNI); (4) motion correction (3dvolreg, AFNI) by registering each volume to the volume most similar, in the least-squares sense, to all others; (5) brain extraction (BET, FSL); (6) rigid body registration to anatomical scans (BBR, FSL); (7) nonlinear registration to the 2 mm Montreal Neurological Institute (MNI) brain (Symmetric Normalization, Advanced Normalization Tools); (8) scrubbing, using a framewise displacement threshold of 0.5 mm, scrubbed volumes were replaced with the mean of the neighboring volumes; (9) 6 mm full width at half maximum Gaussian spatial smoothing (3dBlurInMask, AFNI); (10) 0.01 to 0.08Hz band-pass filtering (3dFourier, AFNI); (11) linear and quadratic detrending (3dDetrend, AFNI) and (12) voxelwise nuisance regression with the six realignment motion regressors and three tissue signal regressors (Ventricles, Freesurfer, eroded in 2 mm space), draining veins (FSL's CSF minus Freesurfer's Ventricles, eroded in 1 mm space) and local white matter (WM) (FSL's WM minus Freesurfer's subcortical gray matter structures, eroded in 2 mm space). Regarding local WM regression, AFNI's 3dLocalstat was used to calculate the mean local WM time series for each voxel, using a 25-mm radius sphere centered on each voxel.

Functional connectivity

Following the preprocessing, a functional atlas was used to separate the cerebral cortex into 100 regions of interest (ROIs)[61]. FC between each pair of ROIs was calculated with a Pearson correlation coefficient between each pair of mean signal 'time courses' (representing fluctuations in neural activity over time). This resulted in an $N \times N$ FC matrix, with each element representing the connectivity strength between a pair of ROIs. Positive values were retained and Fisher-transformed to &zscr; scores. This procedure was repeated independently for each patient and scan (baseline and post-treatment).

Brain network modularity

The community structure or segregation between the brain's functional networks, was measured by summarizing each FC matrix with a common Louvain-like community detection algorithm[62] where the objective is to maximize the extent to which brain areas can be separated into nonoverlapping communities or modules. The modularity quality function score, Q[63], tends to be high when the brain exhibits a high segregation between its functional networks (such as strong clusters of FC within brain networks/communities with weak FC to the rest of the brain).

This approach has been commonly applied to fMRI data to characterize how brain function adapts in a number of contexts[55]. Here, modularity, Q[63], was defined in the standard way by:

$$Q=12m\sum ij(Aij-\gamma kikj2m)\delta(ci,cj),$$

where A_{ij} represents the weight of FC (correlation) between ROI i and j, γ is the structural resolution free parameter (set to 1) and is the expected null FC defined with

as the total FC across all connections with ROI i c_i is the community to which ROI i is assigned,

is the Kronecker δ function and equals 1 if ROI i and j belong to the same community and 0 otherwise[64] and is the total FC of the network.

To allow valid comparisons between patients and scans, the modularity scores were generated 100 times and the partition with the largest modularity score was normalized by the mean modularity generated from 100 randomly rewired (shuffled) FC matrices[65]. This common procedure was applied to account for the nondeterministic and near-degenerate partitions (solutions with differing but similar optimality) generated by Louvain algorithms and to account for modularity scores relating to the total sum of FC within the network[66]. This process was repeated independently for each patient and scan.

Functional cartography

The community detection procedure generates a community assignment to each ROI. We used these labels to determine the extent to which ROIs were recruited to the functional network that they typically 'belong to', as defined by healthy adults (such as DMN regions should reliably form communities with each other).

First, we created an allegiance matrix, P[33], which represented the probability that two regions i and j were assigned to the same community across the 100 iterations of the modularity algorithm, defined here as:

where $O = 100$ as the number of partitions. For each partition, equals 1 if regions i and j belong to the same community.

Using the allegiance matrix, we then summarized how often ROIs either formed communities with ROIs from the same functional network (network recruitment) or formed communities with ROIs between different networks (between-network integration) across the partitions[33]. These functional cartography measures were then normalized against the mean values from 1,000 randomly shuffled ROI network assignments to account for differences in the number of regions in each network[55]. Finally, network recruitment and between-network integration scores were averaged at the network level using seven predefined cortical networks[61].

Dynamic flexibility

The short TR used in the fMRI protocol of study 2 generated approximately twice the number of time points, and this afforded an additional analysis of dynamic flexibility. Multilayer modularity estimation[34] was conducted using a $N \times N \times T$ matrix of 30 volume-sliding windows (37.5 s of real time) with 50% overlap. This window size is typical for estimating dynamic FC with fMRI[54]. For each patient and scan, multilayer modularity, Q_{ML}, was estimated 100 times from each $N \times N \times T$ FC matrix by:

where

is the total FC of the multilayer network, and

is the total FC of layer l, A_{ijl} is the FC between ROI i and j at layer l,

is the expected null FC at layer l. The two free γ and ω structural and temporal resolution parameters are used to scale the number of communities and strength of inter-layer edges, respectively. As is typical for fMRI modularity analyses, both were set to 1 (refs. [33,55]).

The multilayer modularity estimation generates an $N \times T$ matrix where each element represents the community assignment of each ROI at each layer (time window). From this, the flexibility metric, f, can be simply calculated as the number of times an ROI changes its community allegiance, given the number of observations[33]:

Flexibility scores close to 0 represent rigid ROIs whose community allegiance is stable across time, scores close to 1 represent flexible ROIs whose community allegiance regularly changes (highly flexible). Network level flexibility scores were defined by the average flexibility of ROIs assigned to the given network.

Reporting Summary

Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

All requests for raw and analyzed data and materials are promptly reviewed by R.C.H. and D.J.N., chief investigator and principal investigator, respectively, on the original work. Patient-related data not included in the paper were generated as part of clinical trials and may be subject to patient confidentiality. Source data are provided with this paper.

Code availability

All analyses and data visualizations were conducted in MATLAB R2020a. Codes for generating each data figure are available at https://github.com/rdaws/psilodep.

Acknowledgements

R.E.D. was supported by an Engineering and Physical Sciences Research Council PhD scholarship at the Imperial College London Centre for Neurotechnology (EP/L016737/1). The research was carried out at the National Institute for Health Research/Wellcome Trust Imperial Clinical Research Facility. The open-label trial was funded by a Medical Research Council clinical development scheme grant (MR/J00460X/1). The DB-RCT was funded by a private donation from the Alexander Mosley Charitable Trust, supplemented by Founders of Imperial College London's Centre for Psychedelic Research.

Author contributions

This study was designed and planned by R.C.-H. and D.N. and conducted by B.G., M.B.W., D.E. and L.R. The specific analysis was designed by R.E.D. and C.T. The analysis was conducted and visualized by R.E.D. The manuscript was drafted by R.E.D., C.T. and R.C.-H. All authors contributed to the interpretation of the study results and revised and approved the manuscript for intellectual content. Read before the Symposium on Psychedelic Drugs at the 118th annual convention of the American Medical Association, New York, July 17, 1969. Based partially on a presentation by Albert Kurland, MD, at the American College of Neuropsychopharmacology, San Juan, Puerto Rico, Dec 20, 1968.

The history of research with psychedelic drugs has produced a variety of methods for their use and conflicting claims about results. First came the wave of excitement among experimentalists in the 1950s when it was claimed that lysergic acid diethylamide (LSD) could produce a model psychosis which might be useful in understanding schizophrenia. While this promise was fading, enthusiastic reports about the possibility of LSD as an aid to psychotherapy in the treatment of alcoholism and other psychiatric disorders appeared. All these approaches were represented in 1959 at the first international conference devoted entirely to LSD.[1] Since then, there have been at least five more published proceedings of such conferences on various aspects of psychedelic drugs.[2-6] The most recent conference on various means of producing states of consciousness was sponsored by the Menninger Foundation and the American Association of Humanistic Psychology on April 7 to 11, 1969, in Council Grove, Kan, and was called "Voluntary Control Of Internal States."

In the 1960s we have seen research attempts to test scientifically the efficacy and safety of psychedelic drugs for the treatment of various forms of mental illness, chiefly alcoholism. At the same time, there has been a rapidly growing interest concerning these drugs by laymen for pleasure, excitement, mental exploration, and religious experience. The use of psychedelic drugs for all these purposes has produced conflicting claims both in the scientific and popular literature, intense public attention stimulated by the mass media, and legislative attempts at control of both research and the black market.

Effects in Man Facilitated by Psychedelic Drugs

Before we turn to the use of psychedelic drugs as a therapeutic tool, let us review briefly some basic facts. At the outset, it is important to remember that psychedelic drugs are a special class of psychopharmacological agents, not to be confused with sedatives like barbiturates or alcohol, stimulants like amphetamines or methylphenidate hydrochloride (Ritalin), tranquilizers like chlordiazepoxide hydrochloride (Librium) or meprobamate (Miltown), antipsychotic agents like the phenothiazines, or narcotic drugs like the opiates (whether synthetic or natural). Psychedelic drugs in contrast to true narcotics are not physically addicting and produce-quite different psychological experiences from all these other groups of drugs.

What makes psychedelic drugs unique as a class are the psychological phenomena which they facilitate. Five major kinds of potential psychedelic drug experiences have been described in detail with examples elsewhere[7-8] and will only briefly be summarized here.

First is the *psychotic psychedelic experience* characterized by the intense, negative experience of fear to the point of panic, paranoid delusions of suspicion or grandeur, toxic confusion, impairment of abstract reasoning, remorse, depression, and isolation or somatic discomfort or both; all of these can be of very powerful magnitude.

Second is the *cognitive psychedelic experience*, characterized by astonishingly lucid thought. Problems can be seen from a novel perspective, and the inner relationships of many levels or dimensions can be seen all at once. The creative experience may have something in common with this kind of psychedelic experience, but such a possibility must await the results of future investigation.

Third is the *aesthetic psychedelic experience*, characterized by a change and intensification of all sensory modalities. Fascinating changes in sensations and perception can occur: synesthesia in which sounds can be "seen," apparent pulsations or lifelike movements in objects such as flowers or stones, the appearance of great beauty in ordinary things, release of powerful emotions· through music, and eyes-closed visions of beautiful scenes, intricate geometric patterns, architectural forms, historical events, and almost anything imaginable.

Fourth is the *psychodynamic psychedelic experience*, characterized by a dramatic emergence into consciousness of material that was previously unconscious or preconscious. Abreaction and catharis are elements of what may subjectively be experienced as an actual reliving of incidents from the past or a symbolic portrayal of important conflicts.

The fifth and last type of psychedelic experience has been called by various names: *psychedelic peak*, *cosmic*, *transcendental*, or *mystical*, and can be summarized under the following six major psychological characteristics (described in more detail elsewhere7): (1) sense of unity or oneness (positive ego transcendence, loss of usual sense of self without loss of consciousness), (2) transcendence of time and space, (3) deeply felt positive mood (joy, peace, and love), (4) sense of awesomeness, reverence, and wonder, (5) meaningfulness of psychological or philosophical insight or both; and (6) ineffability (sense of difficulty in communicating the experience by verbal description).

The Varieties of Psychedelic Drug Therapies

In the course of experimental therapeutic work with psychedelic drugs (especially LSD), three major approaches have evolved: (1) psycholytic therapy, (2) psychedelic-chemotherapy, and (3) psychedelic-peak therapy. Each of these methods has been described and discussed in detail at the international conference on LSD therapy held in 1965.[3] In any evaluation of therapeutic effects, it is essential to keep in mind the differences in procedure among the various methods, not only because different kinds of experiences are facilitated, but because conflicting results can be correlated with the method used. Reactions to LSD invariably involve a complex interaction between drug dosage, set, and setting.

In psycholytic therapy, which is practiced mainly in Europe, the aim is usually the uncovering of unconscious material which can be psychodynamically analyzed both at the time and in subsequent psychotherapy sessions. There is considerable time spent on psychotherapy before, during, and after the actual drug sessions. This type of therapy is relatively long-term with multiple sessions over time and usually with small doses of the drug (25µg to 150µg).

In psychedelic-chemotherapy, the major emphasis is on administration of the drug itself, during which limited psychotherapy mayor may not be carried out. There is minimal preparation and follow-up therapy. A single session with a relatively high dose of the drug (200µg or more) has been the usual practice, although there have been experiments which consisted of weekly sessions with little or no attempt at help with interpretation or integration. This method is called hypnodelic when hypnotic induction is employed during the preparation for the session or before the onset of drug effects or both with the aim of providing better control. The major differences between psychedelic-chemotherapy and psycholytic therapy are the number of drug sessions, amount of therapy outside the drug sessions, and drug dosage.

In psychedelic-peak therapy, one of the distinctive characteristics and immediate goals in the drug session itself is the achievement of a peak or transcendental experience, but just as important is the intensive psychotherapy which occurs in the weeks prior to the psychedelic drug session and the follow-up therapy in the weeks after to help with the work of integration. The LSD session can add meaningful emotional insight and dramatic validation of an individual's basic self-worth, but usually only after the achievement of psychodynamic resolution and self-understanding during the preparatory psychotherapy. This preparation, which averages about 20 hours per patient, enables the therapist to establish close rapport with the patient and to gain intimate knowledge of the patient's developmental history, dynamics, defenses, and difficulties. In specific preparation for the session itself the patient is encouraged to trust the therapist, himself, and the situation, to let go voluntarily of his usual ego controls and be carried by the experience, and to be completely open to whatever experiences he encounters.

The experimental drug sessions themselves are carried out in a special treatment suite furnished like a comfortable living room, with sofa, easy chairs, rugs, drapes, pictures, flowers, and high-fidelity music equipment. The patient's therapist and a psychiatric nurse are in constant attendance throughout the period of drug action (10 to 12 hours). For most of the session, the patient reclines on the sofa with eyeshades and stereophonic earphones, alternately listening to carefully selected classical music or interacting with his therapist. The function of the music is to help the patient let go more easily, to enter more fully into his unfolding inner world of experience, and to facilitate the release of intense emotionality.

Although the LSD session itself is only one part of psychedelic-peak therapy, it plays a unique and necessary role without which the total therapeutic impact would not be the same. In a dosage of 2000µg or more, LSD produces a 10- to 12- hour period of striking, varied, and anomalous mental functioning; the range of possible effects or episodes of reaction or both is multiform. Certain dimensions of possible reactivity are therapeutically irrelevant (eg. sensory changes) others have distinctly anti therapeutic consequences (eg. panic, terror, or psychotic reactions). The major dimension of drug-altered reactivity with therapeutic relevance is the affective or emotional sphere; intense, labile, personally meaningful emotionality is uniformly produced, with periodic episodes of overwhelming feeling. In terms of sequence of events, the first several hours of a psychedelic session are nonspecific and pervasive; persistent preoccupations and emotional distress patterns are "broken" or fragmented, and subsequent recall for this period is nearly always poor. During the third to fifth hours, psychedelic reactivity usually appears at peak intensity. With skillful handling, the remainder of the session may be stabilized in an elevated mood state in which psychotic and other turbulent phenomena are no longer problems. Follow-up therapy begins during the reentry period of the session day and continues the next day as the patient and therapist review the events of the session and attempt to integrate them. The patient is encouraged to write a detailed description of his experience.

If a psychedelic-peak experience has been achieved and stabilized during the session, a clinical picture which we have termed the psychedelic afterglow can be observed in the days after the session. Mood is elevated and energetic; there is a relative freedom from concerns of the past and from guilt and anxiety, and the disposition and capacity to enter into close interpersonal relationships is enhanced. These psychedelic feelings generally persist for from two weeks to a month and then gradually fade into vivid memories that hopefully will still influence attitude and behavior. During this immediate post-drug period, there is a unique opportunity for effective psychotherapeutic work on strained family or other interpersonal relationships.

It should be emphasized, however, that even with optimal programming, such peak experiences are neither universally achieved nor stabilized, and certainly they do not automatically occur merely by administration of a psychedelic drug. In our research setting,profound or marked psychedelic-peak reactions were judged to have occurred in 68% (56) of 82 consecutive alcoholic patients who received a total of 450µg of LSD given in two equal doses 45 to 60 minutes apart.

Research Projects With Psychedelic-Peak Psychotherapy

Since 1963, at the Spring Grove State Hospital, Baltimore, and now continuing at the Maryland Psychiatric Research Center, research has been in progress to investigate the usefulness of psychedelic-peak psychotherapy with alcoholic, neurotic, and narcotic addict patients and patients who are dying of cancer.9-18 The project which involved alcoholic and neurotic patients, both originally funded by research grants from the National Institute of Mental Health (NIMH) were designed as double-blind, controlled studies. In each project the experimental group received a relatively high dose of LSD (350µg to 450µg) in contrast to only 50µg for the control group; both groups received exactly the same therapeutic preparation. In the study of neurotic patients there was an additional control group of randomly assigned patients who received an equivalent number of hours of group psychotherapy without any LSD. Evaluation of each patient's status was performed by an independent rating team before treatment and at 6, 12, and 18 months following the treatment phase. Full and final analysis and evaluation of these data are still in progress.

Results are now completed at the six-month checkpoint for the study of a total of 135 alcoholic patients who were treated with psychedelic psychotherapy. While the study design made it possible for the patients to have up to three sessions, the vast majority in both experimental and control group (total of 117 patients) received only one treatment with LSD. The 18 patients who had more than one LSD session were not found to be different from the other 117 in psychological and social measures based on pre-treatment testing, but as a group they received more average hours of treatment. Therefore, in the interests of uniformity concerning amount of treatment, results were analyzed separately for the 117 patients who had only one LSD session (either a high or low dose). Out of these 117 patients, 104 were personally located for follow-up interview after six months. It should be noted that the 13 patients not reached for follow-up were properly proportioned according to the original random assignment in which two thirds of the patients were allotted to the high-dose procedure.

Comparison of means before treatment and six months after treatment for global adjustment and drinking behavior are shown in Table 1. Global adjustment included occupational, interpersonal, and residential factors as well as the patient's reaction to alcohol. Ratings were made on each patient on a predetermined 0 to 10 behavior rating scale. The end points of the scale measuring drinking behavior were 0, indicating daily alcohol consumption, and 10 indicating total abstinence. Patients were also categorized according to whether a profound, marked, or minimal psychedelic-peak experience was achieved during the LSD session as rated by the patient's therapist immediately after the session. In Table 1, comparison of means before and after treatment between groups receiving high and low doses and among the psychedelic reactivity groups may be seen to show statistically significant differences using an analysis of covariance statistical procedure (one-tailed test).

The percentage of patients functioning in an "essentially rehabilitated" fashion is shown for the various groups in Table 2. A score of 8 or more on the 0 to 10 scale was considered a rigorous criterion, indicating for global adjustment that a patient was making "good attainment or adjustment" with regard to drinking, occupation, interpersonal relations, etc. A score of 8 on the drinking scale indicated some, but only minimal, departure from total abstinence. Statistical analysis revealed that there were significant differences between the high and low-dose groups in percentage of patients reaching this criterion, both in global adjustment and on the scale measuring drinking. The group of patients with the most profound psychedelic-peak experiences had the highest percentage of patients who showed evidence of rehabilitation. This trend was statistically significant among the three psychedelic reactivity groups for global adjustment, but not for drinking, and thus must be interpreted with caution.

In evaluating these findings in practical terms, we can say that a given alcoholic patient receiving a single high dose of LSD in the context of psychedelic-peak psychotherapy and experiencing a profound psychedelic-peak reaction has the best likelihood for improvement six months later. Within the context of our method, dosage appears to be a more certain outcome predictor than type of experience, although peak experiences do occur more frequently with high doses of LSD. Also the estimation of psychedelic reactivity (from the individual judgments of different therapists) is probably not as reliable as the measurement of therapeutic outcome made by evaluators independent from the treatment team.

Table 1 - Comparison of Means of Alcoholic Patients Receiving One LSD-Session

Patient Group	**Global Adjustment**		**Drinking Behavior**	
	Before Treatment	6 mo After Treatment	Before Treatment	6 mo After Treatment
Dosage High (N = 64)	4.16	6.52	2.83	7.02
Low (N = 40)	3.28	5.13	2.93	5.75
Psychedelic reactivity Profound (N =31)	4.43	7.13	2.65	7.52
Marked (N = 31)	3.87	6.16	2.94	6.94
Minimal (N = 50)	3.50	5.34	2.92	5.82
Results of Covariance Analyses For Above Data	*F*	*P**	*F*	*P**
High dose vs low dose	3.76	0.05	4.43	0.025
Psychedelic reactivity groups	2.42	0.05	3.09	0.025

* P values are for one-tatted tests of significance.

An NIMH-sponsored project to investigate the effect of psychedelic-peak psychotherapy with narcotic addicts is well underway, but it is too early for any indication of therapeutic outcome. These patients in general seem to have a greater degree of psychopathology than the alcoholics with whom we have worked, but the skilled implementation of psychedelic psychotherapy seems to be proceeding smoothly. An observation of interest is that the character of the drug experience with LSD has been reported by the addicts to be distinctly and qualitatively different from what they experienced under heroin (ie, a confrontation with their problems rather than an escape from them).

During the past several years, we have also been exploring the potential of psychedelic-peak psychotherapy with patients with cancer.[16-18] The purpose has been to treat the depression, anxiety, psychological isolation, and intractable pain which so many of these patients face. The families, too, must cope with psychological problems which relate to their own fears and impending sense of loss. How to relate to the patient and what to tell him about his diagnosis further complicates what is already a grim situation. This use of LSD is similar to that already outlined, except that not quite as much time is spent in preparation, and the treatment takes place in a private room of a general medical facility (Sinai Hospital, Baltimore). Also, family therapy plays a larger role.

Thus far, we have treated 35 patients in a pilot project. Our findings must remain only suggestive at this point, but they do give some promising indications of the potential of this form of treatment. Measurements before and after LSD on depression, anxiety, emotional tension, psychological isolation, fear of death, and amount of medication required for pain have shown change in a positive direction in about two-thirds of the patients. In half of these the improvement was dramatic, and those patients who had the most profound peak experiences tended to show the most benefit. Also, patients treated earlier in the course of their disease were able to use the experience more rewardingly.

While not all patients were helped dramatically, none, even the most ill, appeared to have been harmed. This finding in regard to the safety of the procedure has been consistent with our results in alcoholic and neurotic patients.

The following case summary will serve to illustrate both the method and possible outcome.

Table 2 - Acoholic Patients Improved Six Months After One LSD Session

Patient Group	**No. of Patients With Global Adjustment Scores of 8, 9, or 10 (%)**	**No. of Patients With Drinking Behavior Scores of 8, 9, or 10 (%)**
Dosage High (N = 64)	44 (28/64)	53 (34/64)
Low (N = 40)	25 (10/40)	33 (13/40)
Psychedelic reactivity Profound (N = 23)	61 (14/23)	61 (15/23)
Marked (N = 31)	39 (12/31)	48 (48/31)
Minimal (N = 50)	24 (12/50)	36(18/5)

X^2 Results For Above Data

	Global Adjustment		**Drinking Behavior**	
	X^2	*P**	X^2	*P**
High vs low dose	2.97	0.05	3.44	0.05
Psychedelic reactivity groups	7.74	0.025	3.07	Not significant

* *P* values are for one-tailed tests of significance.

Report of a Case

The patient, a 58-year-old Jewish married woman, had suffered from cancer of the breast for 12 years. In spite of numerous surgical and medical procedures which included hysterectomy, oophorectomy, and adrenalectomy, the disease had spread widely in her spine. At the time she was referred for LSD treatment, pressure on nerves in her spine had caused numbness and a paralysis of the lower half of her body. When first interviewed, the patient was anxious and depressed.

After six hours of preparatory psychotherapy with the patient and her family. over the period of a week, during which the nature and purpose of the treatment was explained, the patient was given 300 µg of LSD. The first few hours of her psychedelic session went well and were pleasant, but a complete psychedelic-peak experience was not obtained. There were a few moments of intense positive psychedelic reactivity; for example, at one point the patient exclaimed, "This is one of the happiest days of my life. I will always remember it." There were also transient episodes of apprehension, confusion, and paranoia which were easily handled by reassurance and support.

During the latter part of the session, the patient raised the question of whether or not she would walk again. This issue was handled by a realistic review of the patient's condition, and the therapist finally stated in a direct answer to her question that it was very· unlikely that she would be able to walk again. The patient then expressed her reluctant acceptance of the idea that her life could still go on even if she were confined to bed, a condition which she had previously greatly feared. However, the patient spontaneously expressed her determination to try her best in physiotherapy, in spite of the odds against her. She was supported in her resolve to try, but also discussed was acceptance of her condition, if it could not be improved. During the evening after the patient had emerged from the effects of the drug, the patient's family visited. This was a time of intense closeness and interpersonal sharing. The family remarked on the change in her mental condition from that of anxiety and depression to one of peace and joy.

In the days after the session the patient's mood was cheerful and hopeful. Upon discharge from the hospital six days after her LSD treatment, the patient returned home and began intensive work with a physiotherapist. She made remarkable, quite unexpected progress and within four months was able to use a walker. Six months after treatment the patient was doing some limited walking with a cane.

In spite of her impressive accomplishments, the patient again became depressed and difficult to manage at home because of her feelings that she would always be an invalid. She was especially distressed because the back-brace which she had to wear out of bed (four to six hours a day) was cumbersome and she needed assistance by another person in order to put it on. Because of her increasing depression, both the patient and her family requested another LSD treatment. She was seen regularly for preparation. Interpersonal relations, her self-concept, and some realistic expectations for the future were the major issues explored.

Ten months after her first session the patient was readmitted to the hospital for her second LSD treatment. Her initial reaction to the session was one of anxiety, and then the issue of her disease was encountered. She faced the fact that throughout her illness she had tended to deny that she was really sick. She remembered patients she had known with cancer, and her fear of decaying flesh was symbolized by visions of vultures feeding on rotten meat. After confronting rather than retreating from these unpleasant feelings and experiences, the patient had the experience of passing through a series of blue curtains or veils. On the other side she felt as if she were a bird in the sky soaring through the air. Then she was on a high mountain top in a small cabin alone with the snow falling. She experienced wonderful feelings of peace and harmony and visions of beautiful colors like the rainbow. After this, she stabilized the experiences and had enjoyable reliving of happy memories from her past, the best of which was her wedding day, which she relived in great detail including a reexperience of the way her mother sighed as she came down the aisle. These happy memories were in contrast to the early part of her experience when she had relived some unpleasant events such as the prejudice she felt against her as a child because she was Jewish and her failure to take advantage of the cultural opportunities her father had provided. In the latter part of the experience the patient thought deeply about her family while looking at their pictures. She was able to resolve some of the ambivalence she had about her younger daughter who was to be married in three months. She felt sorry for some of the strife they had had and came out of the experience with a resolve to make a more constructive attempt to relate to this girl in the future. When the patient's family arrived after supper, she had a serene smile on her face, but was reluctant to talk about her experience too much. She said, "You wouldn't believe me if I did tell you."

Subsequently, the patient left the hospital in good spirits and was able to participate actively in her daughter's wedding. She fulfilled her desire to walk down the aisle without the aid of even a cane, and during the wedding reception she amazed all the guests by dancing with her husband. Her sister said she had been the life of the party.

Table 3 - Means of Chromosomal Aberration Rates* Before and After LSD Among Various Experimental Groups

Group	**Before LSD**	**After LSD**	**Difference**	***P***
32 patients	4.28	5.91	+1.63	Not significant†
5 users	2.81	3.57	+0.76	Not significant‡
8 experimental subiects	...	2.79	...	...
2 normal subjects	2.65	...	...	...

*Aberration rate = percentage of aberrant cells/total metaphases analyzed (at least 200 per culture).
† Wilcoxon matched-pairs, signed-ranks, two-tailed test.
‡ Fisher exact probability test.

Within six months the patient requested a third LSD treatment. At this time she had increasing pain and was discouraged because she had not worked in over two years although she had kept the hope alive that she would eventually return to her old job. The session began smoothly but the patient became frightened when she saw a huge wall of flames. After support and encouragement by the therapist, the patient was able to go through the middle of the flames, and at this point experienced positive ego transcendence. She felt that she had left her body, was in another world, and was in the presence of God which seemed symbolized by a huge diamond-shaped iridescent Presence. She did not see Him as a Person but knew He was there. The feeling was one of awe and reverence, and she was filled with a sense of peace and freedom. Because she was free from her body, she felt no pain at all. She was quiet during most of the day and emerged from the session with a deep feeling of peace and joy. When her family had arrived, she radiated a psychedelic afterglow of peace and beauty which all remarked upon. During the course of the evening the patient had a serious talk with her daughters about her condition and what might lie ahead. Shortly thereafter the patient was discharged from the hospital in good spirits. One effect of the treatment was that when the patient was troubled with pain, she could push the pain out of her mind by remembering her out-of-the-body LSD experience.

The patient did very well for about one month, until she slipped on the stairs one day and injured her back, which began causing her considerable pain again. She also became sick with influenza and was confined to bed. Prior to this she had been considering going back to work at her old job, part-time, but with the worsening of her physical condition these plans had to be postponed. With these physical setbacks and especially the recurrence of her pain, the patient again became somewhat depressed. Both the patient and her family requested another LSD treatment. The patient was seen weekly for about a month as an outpatient, and then readmitted for a treatment with LSD, almost six months after her third treatment.

The evening before her session, during the final preparation, the patient suddenly asked a direct question about her diagnosis for the first time in the almost two years she had been in the LSD-treatment program. Although she knew that her breast had been removed for a tumor, she had believed there was no further growth, but the increasing pain in her back had made her wonder. Her questions were answered gently, but without evasion, and the meaning and emotional impact were discussed with her. The family members were informed of this conversation immediately thereafter, and they reacted by becoming quite upset and angry. That very evening, in a general family discussion with the patient and therapist, however, most of them were able to resolve their feelings. Some felt embarrassed because of their previous pretense; most felt relieved when they saw how well the patient had dealt with the situation. The patient stated that she was glad to know the truth and was obviously not psychologically shattered or further depressed as some of the family members had feared.

The fourth session the next day went smoothly, except for some nausea which was experienced shortly before admission when she had eaten some spoiled food. Much psychodynamic material emerged concerning her feelings about various members of her family, especially her two daughters. In the evening the patient felt very close to her family and spent some time in talking to each of them alone in a very personal way. She was reluctant to have them leave at the end of the evening, even though she was very tired. In the days after the session the patient felt relaxed and in good spirits. She was not pessimistic about the future, in spite of the new knowledge about the diagnosis of metastatic cancer of the spine. She was able to tolerate the pain in the back with the aid of narcotic drugs, but did not have complete relief from pain.

While still in the hospital, an hypophysectomy was attempted as a possible means to stop further spread of her metastatic process. Because of hemorrhage the operation could not be completed, and the patient died a few days later.

This patient experienced considerable relief from pain, depression, and anxiety over the period of almost two years during which she received four LSD treatments. Her first session was not judged to have had much psychedelic content, but the second, third, and fourth sessions did. The third session was the most complete psychedelic-peak experience and seemed to provide the most benefit. This patient's gratifying physical improvement can be attributed only indirectly to the LSD treatment in that her own underlying resolution to pursue physiotherapy emerged when her depression and anxiety were relieved. By a fortunate coincidence, her condition responded well to these efforts on her part, contrary to the most informed medical prognosis. All our patients are told that LSD is for treatment of psychological distress and not a cure for their physical disease. In this case, as happens not infrequently, sometime during the course of LSD treatment the issue of diagnosis was brought up by the patient and had to be worked out with the patient and the family.

The Question of Safety

When psychedelic drugs are administered under controlled medical conditions (as has been the case in several large-scale research projects in recent years), permanent adverse effects have been rare. Since 1963, at the Spring Grove State Hospital and now at the Maryland Psychiatric Research Center, Baltimore, over 300 patients have been treated with LSD without a single case of long-term psychological or physical harm directly attributable to the treatment, although there have been two cases in which disturbances persisted in the days following the actual LSD session. Both patients subsequently responded to conventional psychiatric treatment.

Throughout the years of research with LSD many possible harmful physical effects have been suggested, but careful subsequent investigation has failed to furnish much conclusive scientific evidence. Most recently, the question of chromosomal damage has been raised following the positive *in vitro* findings in white blood cells by Cohen.[19] Retrospective studies on persons having taken LSD (most from the black market and only a few under medical supervision) have produced conflicting reports. Some researchers[20-22] found increased chromosomal breakage over normal rates, and others no Increase.[23-25]

Because we were in a position to study the effect of pure LSD of known amount on patients who were to be treated with psychedelic psychotherapy, we entered into collaboration with the cytogenetics laboratory of Joe-Hin Tjio, PhD, at the National Institute of Arthritis and Metabolic Diseases to carry out a rigorously controlled study. Blood samples from 32 patients being treated at the Spring Grove State Hospital were drawn and cultured both before and after LSD administration. The white blood cell (WBC) chromosomes were then studied without prior identification of the slides, and at least 200 metaphases were analyzed per culture. In addition, the WBC chromosomes of five chronic LSD users were studied before, during, and after the administration of known doses of LSD in research on sensory, cognitive, and perceptual functions at the National Institutes of Health.

No difference was found in the rate of chromosomal aberrations before and after administration of LSD when the data from these 37 separate individuals were statistically analyzed. Also, chromosomal analysis after LSD administration was done on eight normal subjects who had received LSD in research experiments in the past, and no increase over normal chromosomal breakage rate was found. A summary of these results is presented in Table 3. The mean rates before LSD in the 32 patients (4.28%) and the five LSD users (2.81%) are comparable to each other and to the values obtained from samples from two normal control subjects for eight to ten consecutive days (2.65%). The differences between the rates before and after receiving LSD for both the 32 patients (+1.63%) and the five LSD users (+0.76%) are not statistically significant. The mean chromosomal aberration rates for the 32 patients and five LSD users (including those both before and after administration of LSD), eight experimental LSD subjects (after LSD administration), and two normal controls (no LSD) only vary from 2.65% to 5.91%. Detailed reports of this research have been presented and published.[26,27]

Comment

Part of the conflicting evidence about the efficacy of psychedelic drugs as a therapeutic tool for the treatment of mental illness comes from the differences in the methods employed by various groups of researchers. Unfortunately, rather than replicating each other's methods, each research team seems to have developed its own procedure.

In spite of such diversity of approach, several points seem to be clear by now. Use of LSD is not a substitute for skilled psychotherapy. Experiments where LSD was used primarily as a chemotherapeutic agent or with a minimum of psychotherapy have not shown any greater efficacy regarding therapeutic outcome, especially with alcoholics, than control groups."e- 3! The evidence from the psycholytic use of LSD by European researchers and psychedelic-peak therapy as practiced at the Maryland Psychiatric Research Center indicates that LSD can be an enhancer of skilled psychotherapy when integrated with an intensive psychotherapeutic program of sufficient duration (30 to 50 hours).

The scientific evidence concerning possible genetic hazards of LSD is conflicting and inconclusive. The difference in results between our carefully controlled study before and after administration of LSD in patients and the research on LSD abusers may be explained by the many uncontrolled variables such as viral infections and the effects of other drugs. Certainly much more research needs to be done in this complex area before valid conclusions can be drawn.

Research with psychedelic drugs needs to be continued to learn more about their effective use. Questions need to be answered, such as what kinds of patients will benefit most and under what circumstances. As our research progresses and we gain more experience we expect to modify our implementation of psychedelic-peak psychotherapy. Newer psychedelic drugs may have certain advantages over more well-known ones. For example, we have been testing dipropyltryptamine (DPT) developed by Szara[32] at the NIH, which has a duration of action of from two to four hours depending on dosage. If this drug proves to be as effective and safely manageable as the much longer-acting LSD, it could result in a psychedelic procedure that could be more flexibly and easily implemented than that with LSD.

In spite of the potential uses for psychedelic drugs suggested by our work, the future of such research, unfortunately, seems uncertain. Contributing factors for this dim prognosis are sensationalism of the effects of LSD along with a continuing spread of illicit use, public fear stimulated especially by reports of irreversible genetic and psychological damage, the decreasing amount of research being initiated, the dearth of investigators who have had first-hand clinical or research experience with LSD, and the difficulty of obtaining such training.

Our hope is that the current public concern over abuse can give way to a resurgence of careful and informed research including specialized training and experience for those interested in this area. Our past and present research continues to intrigue us with the promise of psychedelic drugs, but they are obviously powerful tools that need to be used and handled wisely. Hopefully, it is not too late for them to be harnessed for medical and research use in a variety of ways in the future.

These investigations were supported in part by Public Health Service research support grants MH-13747 (Psychedelic Therapy Research Program), MH-15555 (Program for Treatment of the Narcotic Addict), MH-08474 (Controlled Study of LSD Therapy with Alcoholics), MH-1100l (A Controlled Study of LSD Therapy with Neurotics), and FR-05546 (General Research Support Program). These grants were administered by Friends of Psychiatric Research, Inc, Baltimore.

The lysergic acid diethylamide used in this research was manufactured by the Sandoz Pharmaceutical Co., Basel, Switzerland, and distributed by the FDA-NIMH Committee for psychomimetic drug research.

Lee McCabe, PhD, Sidney Wolf, MA, William Richards, STM, and Thomas Cimonetti, MD, collaborated in these studies. James Olsson, PhD, performed the statistical analyses. Harry Shock, LLB, headed the independent evaluation follow-up team. Louis Goodman, MD, Sinai Hospital, Baltimore, Md, arranged the clinical facilities for the study of patients with cancer.

List of tables

Preface
Chapter I - INTRODUCTION
Chapter II - RELIGION AND PSYCHEDELIC SUBSTANCES: A SURVEY
 Data from History, Archaeology, Anthropology, Botany, and Psychopharmacology
 Data from Clinical Research
Chapter III - THE DEFINITION OF MYSTICISM
 Mystical Experience in General
  The Relationship between Mystical Experience and Religious Experience
  The Universality of the Characteristics of Mystical Experience
  Primary Experience versus Interpretation
 Phenomenological Typology of Mystical States of Consciousness
  Category I: Unity
   Internal Unity
   External Unity
  Category II: Transcendence of Time and Space
  Category III: Deeply Felt Positive Mood
  Category IV: Sense of Sacredness
  Category V: Objectivity and Reality
  Category VI: Paradoxicality
  Category VII: Alleged Ineffability
  Category VIII: Transiency
  Category IX: Persisting Positive Changes in Attitude and/or Behavior
 The Continuum of Mystical Experiences
Chapter IV - EXPERIMENTAL DESIGN
 Non-drug Factors
 Choice of Drug
 Recruitment and Pre-testing of Subjects
 Preparation and Grouping of Subjects
 Experimental Procedure
  Drug Preparation
  Protocol During the Experimental Day
 Collection of Data after the Experiment
Chapter V - DATA USED IN MATCHING OF SUBJECTS
 Pre-drug Questionnaire and Interview Data
  Rating Scale
  Categories
  Description of Average Subject
 California Psychological Inventory Data
Chapter VI - DATA FROM QUESTIONNAIRES, INTERVIEWS, AND CONTENT ANALYSES
 Data Relevant to the Categories of the Typology of Mysticism
  Method of Presentation
  Category I: Unity
   Internal Unity
   External Unity
   Supplementary Phenomena
  Category II: Transcendence of Time and Space
  Category III: Deeply Felt Positive Mood
   The most universal phenomena (Joy, Blessedness, and Peace)
   Closely Related Phenomena (Love)
  Category IV: Sense of Sacredness
  Category V: Objectivity and Reality
  Category VI: Paradoxicality

Category VII: Alleged Ineffability
Category VIII: Transiency
Category IX: Persisting Positive Changes in Attitude and Behavior
Changes toward self
Changes toward others
Changes toward life
Changes toward the experience
Other Data
Chapter VII - GENERAL DISCUSSION AND CONCLUSIONS
Discussion of Design
Observations of the Experimenter during the Experiment
Summary and Discussion of Data
Conclusions
Chapter VIII - SUGGESTIONS FOR FURTHER RESEARCH AND IMPLICATIONS FOR THE FUTURE
Appendix A - MEDICAL HISTORY FORM FOR VOLUNTEER SUBJECTS FOR PSILOCYBIN RESEARCH
Appendix B - PRE-DRUG EXPERIENCE QUESTIONNAIRE
Appendix C - POST-DRUG QUESTIONNAIRE WITH SIGNIFICANCE LEVELS OF THE DIFFERENCE BETWEEN SCORES OF EXPERIMENTALS AND CONTROLS
Appendix D - FOLLOW-UP QUESTIONNAIRE WITH SIGNIFICANCE LEVELS OF THE DIFFERENCE BETWEEN SCORES OF EXPERIMENTALS AND CONTROLS
Section I
Section II
Section III
Appendix E - CONTENT ANALYSIS
Content Analysis Instruction Manual for Judges
Content Analysis Score Sheet Used by Judges with the Probability for each Item that the Difference between Experimentals and Controls was due to Chance
Reliability of Judges as Determined from Kendall Rank Correlation Coefficient
Appendix F - EXPLANATION OF THE COLUMNS AND SYMBOLS USED IN THE CATEGORY TABLES
Appendix G - DATA NOT DIRECTLY RELEVANT TO CATEGORIES OF THE TYPOLOGY OF MYSTICISM
Group I: Integrative and Constructive Phenomena
Group II: Disturbing Changes in Attitude and Behavior
Group III: Physical Sensations
Group IV: Miscellaneous
Bibliography

LIST OF TABLES

1. Data Used in Matching Pairs of Subjects from Pre-Drug Questionnaires and Interviews
2. From the California Psychological Inventory: Relevant Scores Used in Matching Pairs of Subjects
3. Category I: Unity (Combination of All Subcategories)
4. Category I: Unity (Internal Unity)
5. List of Items Used to Measure Internal Unity
6. Category I: Unity (External Unity)
7. List of Items Used to Measure External Unity
8. Category I: Unity (Supplementary Phenomena)
9. List of Supplementary Phenomena of Unity
10. Category II: Transcendence of Time and Space (Combination of all Subcategories)
11. Category II: Transcendence of Time and Space
12. List of Items Used to Measure Transcendence of Time and Space
13. Category III: Deeply Felt Positive Mood (Combination of all Subcategories)
14. Category III: Deeply Felt Positive Mood (Most Universal phenomena: joy, blessedness, & peace. Less universal: Love)
15. List of Items Used to Measure the Most Universal Phenomena of Deeply Felt Positive Mood (Joy, Blessedness, and Peace)
16. List of Items Used to Measure Love

17. Category IV: Sense of Sacredness (Combination of all Subcategories)
18. List of Items Used to Measure Sense of Sacredness
19. Category IV: Sense of Sacredness (Phenomena with Implicit Indication of Sense of Sacredness. Phenomena which Explicitly Mention the Holy, Sacred, and Divine)
20. Category V: Objectivity and Reality
21. List of Items Used to Measure Objectivity and Reality
22. Category VI: Paradoxicality (Combination of all Items)
23. List of Items Used to Measure Paradoxicality
24. Category VII: Alleged Ineffability (Combination of all Items)
25. List of Items Used to Measure Alleged Ineffability
26. Category VIII: Transiency (Combination of all Phenomena. Essential Phenomena)
27. List of Items Used to Measure Transiency
28. Category IX: Persisting Positive Changes after Six Months
29. List of Items Used to Measure Persisting Positive Changes in Attitude and Behavior
30. Category IX: Persisting Changes *Toward Self* after Six Months (Persisting POSITIVE changes. Persisting NEGATIVE Changes)
31. Category IX: Persisting Changes *Toward Others* after Six Months (Persisting POSITIVE changes. Persisting NEGATIVE Changes)
32. Category IX: Persisting Changes *Toward Life* after Six Months (Persisting POSITIVE changes. Persisting NEGATIVE Changes)
33. Category IX: Persisting Changes *Toward Experience* after Six Months (Persisting POSITIVE changes. Persisting NEGATIVE Changes)
34. Summary of Significance levels Reached by Experimental Group for Categories Measuring the Typology of Mysticism
35. Summary of Data Measuring Degree of Completeness or Intensity of Categories of the Typology of Mysticism

Acknowledgments

The author wishes to express his deep gratitude for the support and encouragement of many members of the academic community who made this study possible in a troubled but promising area of research. Particular appreciation is extended to Dr. Hans Hofmann, who was a continuing source of counsel and inspiration, and to Dr. Timothy Leary, who assisted with the execution of the experiment. Through the guidance of the thesis committee, the author's perspectives have been clarified and deepened. Mr. Peter H. John contributed much time and tireless effort toward the mechanics of the manuscript. Finally, the author desires sincerely to thank all the persons who volunteered to participate in this investigation as experimental subjects or group leaders.

Preface

**This section was untitled in original work. "Preface" was added to non-sheet html version.*

This dissertation was an empirical study designed to investigate the similarities and differences between experiences described by mystics and those induced by psychedelic (or mind-manifesting) drugs such as d-lysergic acid diethylamide (LSD), psilocybin, and mescaline. First, a phenomenological typology of the mystical state of consciousness was carefully defined after a study of the writings of the mystics themselves and of scholars who have tried to characterize mystical experience. Then, some drug experiences were empirically studied, not by collecting such experiences wherever an interesting or striking one might have been found and analyzed after the fact, but by conducting double-blind, controlled experiments with subjects whose religious background and experience as well as personality had been measured *before* their drug experiences. The preparation of the subjects, the setting under which the drug was administered, and the collection of data about the experience were made as uniform as possible. The experimenter himself devised the experiment, collected data, and evaluated the results without ever having had an experience with any of these drugs.

The long and continuing history of the religious use of plants which contain psychedelic substances was surveyed. In some instances, such natural products were ingested by a priest, shaman, or witch doctor to induce a trance for revelatory purposes; sometimes they were taken by groups of people who participated in sacred ceremonies. For example, the dried heads of the peyote cactus, whose chef active ingredient is mescaline, were used by the Aztecs at least as early as 300 B.C. and are currently being employed by over 200,000 Indians of the North American Native Church as a vital part of their religious ceremonies. Both *ololiuqui*, a variety of morning glory seed, and certain kinds of Mexican mushrooms (called *teonanacatl*, "flesh of the gods") were also used for divinatory and religious purposes by the Aztecs. These practices have continued to the present among remote Indian tribes in the mountains of southern Mexico. Modern psychopharmacological research has shown the active chemicals to be psilocybin in the case of the mushrooms, and several compounds closely related to LSD in the case of *ololiuqui*. *Amanita muscaria*, the mushroom which has been used for unknown centuries by Siberian shamans to induce religious trances, does not contain psilocybin. The most important psychologically active compound from this mushroom has not yet been isolated. Other naturally-occurring plants, which are used by various South American Indian tribes in in a religious manner for prophecy, divination, clairvoyance, the tribal initiation of male adolescents, or sacred feasts, are cohobe snuff made from the pulverized seeds of *Piptadenia* (a tree); the drink, *vinho de Jurumena*, made from the seeds of *Mimosa hostilis* (a tree); and the drink, *caapi*, made from *Banisteriopsis* (a jungle creeper). These last three products contain various indolic compounds which are all closely related to psilocybin, both structurally and in their psychic effects (e.g., dimethyltryptamine, bufotenine, and harmine).

Some of the researchers who have experimented with synthesized mescaline, LSD, or psilocybin have remarked upon the similarity between drug-induced and mystical experiences because of the frequency with which some of their subjects have used mystical and religious language to describe their experiences. Our study was an attempt to explore this claim in a systematic and scientific way.

The nine-category typology of the mystical state of consciousness was defined as a basis for measurement of the phenomena of the psychedelic drug experiences. Among the numerous scholars of mysticism, the work of W. T. Stace[1] was found to be the most helpful guide for the construction of this typology. His conclusion that in the mystics experience there are certain fundamental characteristics which are universal and are not restricted to any particular religion or culture (although particular cultural, historical, or religious conditions may influence both the interpretation and description of these basic phenomena) was taken as a presupposition. Whether or not the mystical experiences is "religious" depends upon one's definition of religion and was not the problem investigated. Our typology defined the universal phenomena of the mystical experience, whether considered "religious" or not.

The nine categories of our phenomenological typology may be summarized as follows:

Category I: **Unity**
Unity, the most important characteristic of the mystical experience, is divided into internal and external types, which are different ways of experiencing an undifferentiated unity. The major difference is that the internal type finds unity through an "inner world" *within* the experiencer, and the external type finds unity through the external world *outside* the experiencer.

The essential elements of *internal unity* are loss of usual sense impressions and loss of self without becoming unconscious. The multiplicity of usual external and internal sense impressions (including time and space) and the empirical ego or usual sense of individuality fade or melt away while consciousness remains. In the most complete experience this consciousness is a pure awareness beyond empirical content, with no external or internal distinctions. In spite of the loss of sense impressions and dissolution of the usual personal identity or self, the awareness of oneness or unity is still experienced and remembered. One is not unconscious, but rather very much aware of an undifferentiated unity.

External unity is perceived outwardly with the physical senses through the external world. A sense of underlying oneness is felt behind the empirical multiplicity. The subject or observer feels that the usual separation between himself and an external object (inanimate or animate) is no longer present in a basic sense, yet the subject still knows that on another level, at the same time, he and the objects are separate. Another way of expressing this same phenomenon is that the essences of objects are experienced intuitively and felt to be the same at the deepest level. The subject feels a sense of oneness with these objects because he "sees" that at the most basic level all are a part of the same undifferentiated unity. In the most complete experience a cosmic dimension is felt so that the experiencer feels in a deep sense a part of everything that is.

Category II: **Transcendence of Time and Space**
This category refers to loss of the usual sense of time and space. Time means clock time but may also be one's personal sense of his past, present, and future. Transcendence of space means that a person loses his usual orientation as to where he is during the experience in terms of the usual three-dimensional perception of his environment. Experiences of timelessness and spacelessness may also be described as an experience of "eternity" or "infinity".

Category III: **Deeply Felt Positive Mood**
The most universal elements (and therefore, the ones which are most essential in the definition of this category) are joy, blessedness, and peace. Their unique character in relation to the mystical experience is that their intensity marks them as being at the highest levels of the human experience of these feelings, and they are valued highly by the experiencers. Tears may be associated with any of these elements because of the overpowering nature of the experience. These feelings may occur at the peak of the experience or during the "ecstatic afterglow" when the peak has passed, but its effects and memory are still quite vivid and intense. Love may also be an element of deeply felt positive mood, but does not have the same universality as joy, blessedness, and peace.

---

[1] W. T. Stace. Mysticism and Philosophy (Philadelphia and New York: J. B. Lippincott, 1960).

Category IV: **Sense of Sacredness**
This category comprises the sense of sacredness which is evoked by the mystical experience. The sacred is here defined broadly as that which a person feels to be of special value and capable of being profaned. The basic characteristics of sacredness is a non-rational, intuitive, hushed, palpitant response of awe and wonder in the presence of inspiring realities. No religious "beliefs" or traditional theological terminology need necessarily be involved even though a sense of reverence or a feeling that what is experienced is holy or divine may be included.

Category V: **Objectivity and Reality**
This category has two interrelated elements: (1) insightful knowledge or illumination felt at an intuitive, non-rational level and gained by direct experience and (2) the authoritativeness of the experience or the certainty that such knowledge is truly real, in contrast to the feeling that the experience is a subjective delusion. These two elements are connected because the knowledge through experience of ultimate reality (in the sense of being able to "know" and "see" what is really *real*) carries its own sense of certainty. The experience of "ultimate" reality is an awareness of another dimension not the same as "ordinary" reality (The reality of usual, everyday consciousness), yet the knowledge of "ultimate" reality is quite real to the experiencer. Such insightful knowledge does not necessarily mean an increase in facts, but rather intuitive illumination. What becomes "known" (rather than only intellectually assented to) is intuitively felt to be authoritative, requires no proof at a rational level, and has an inward feeling of objective truth. The content of this knowledge can be divided into two main types: (a) insights into being and existence in general, and (b) insights into one's personal, finite self.

Category VI: **Paradoxicality**
Accurate descriptions and even rational interpretations of the mystical experience tend to be logically contradictory when strictly analysed. For example, in the experience of internal unity there is a loss of all empirical content in an *empty* unity which is at the same time *full* and complete. This loss includes the loss of the sense of self and dissolution of individuality, yet something individual remains to experience the unity. The "I" both exists and does not exists. Another example is the separateness from, yet at the same time unity with, objects in the experience of external unity (essentially a paradoxical transcendence of space).

Category VII: **Alleged Ineffability**
In spite of attempts to tell or write about the mystical experience, mystics insist that words fail to describe it adequately or that the experience is beyond words. Perhaps the reason is an embarrassment with language because of the paradoxical nature of the essential phenomena.

Category VIII: **Transiency**
Transiency refers to duration and means the temporariness of the mystical experience in contrast to the relative permanence of the level of usual experience. There is a transient appearance of the special and unusual levels or dimensions of consciousness which are defined by our typology, but eventual disappearance and return to the more usual. The characteristic of transiency indicates that the mystical state of consciousness is not sustained indefinitely.

Category IX: **Persisting Positive Changes in Attitude and/or Behavior**
Because our typology is of a healthful, life-enhancing mysticism, this category describes positive, lasting effects which are the result of the experience. These changes are divided into four groups: (1) toward self, (2) toward others, (3) toward life, and (4) toward the mystical experience itself.

(1) Increased integration of personality is the basic inward change in the personal self. Undesirable traits may be faced in a way that enables them to be dealt with and finally reduced or eliminated. Issuing from personal integration, the sense of one's inner authority may be strengthened, and the vigor and dynamic quality of a person's life may be increased. Creativity and greater achievement efficiency may be released. There may be an inner optimistic tone with consequent increase in feelings of happiness, joy, and peace. (2) Changes in attitude and behavior toward others include more sensitivity, more tolerance, more real love, and more authenticity as a person by being more open and more one's true self with others. (3) Changes toward life in a positive direction include philosophy of life, sense of values, sense of meaning and purpose, vocational commitment, need of service to others, and new appreciation for life or the whole of creation. Life may seem richer. The sense of reverence may be increased, and more time may be spent in devotional life and

meditation. (4) Positive change toward the experience means that it is regarded as valuable and that what has been learned is thought to be useful. The experience is remembered as a high point, and an attempt is made to recapture the experience, or if possible, to gain new experiences as a source of growth and strength. Mystical experiences of others are more appreciated and understood.

The purpose of the experiment in which psilocybin was administered in a religious context was to gather empirical data about the state of consciousness experienced. In a private chapel on Good Friday twenty Christian theological students, ten of whom had been given psilocybin one-and-one-half hours before, listened over loud speakers to a two-and-one-half-hour religious service which consisted of organ music, four solos, readings, prayers, and personal meditation. The assumption was made that for experiences most likely to be mystical, the atmosphere should be broadly comparable to that achieved by tribes who actually use natural psychedelic substances in religious ceremonies. The particular content and procedure of the ceremony had to be applicable (i.e. familiar and meaningful) to the participants. Attitude toward the experience, both before and during, was taken into serious consideration in the experimental design. Preparation was meant to maximize positive expectation, trust, confidence, and reduction of fear. Setting was planned to utilize this preparation through group support and rapport friendship, an open and trusting atmosphere, and prior knowledge of the procedure of the experiment in order to eliminate, if possible, feelings of manipulation which might arise.

In the weeks before the experiment each subject participated in five hours of various preparation and screening procedures which included psychological tests, medical history, physical exam, questionnaire evaluation of previous religious experience, intensive interview, and group interaction. The twenty subjects were graduate-student volunteers, all of whom were from middle-class Protestant backgrounds and from one denominational seminary in the free-church tradition. None of them had ever taken psilocybin or related substances before this experiment. The volunteers were divided into five groups of four student each on the basis of compatibility and friendship. Two leaders who knew from past experience the positive and negative possibilities of the psilocybin reaction meat with their groups to encourage trust, confidence, group support, and fear reduction. The method of reaction to the experience was emphasized (i.e. to relax and cooperate with, rather than to fight against, the effects of the drug). Throughout the preparation an effort was made not to suggest the characteristics of the typology of mysticism.

Double-blind technique was employed in the experiment so that neither the experimenter nor any of the participants (leaders or subjects) knew the specific contents of the capsules which were identical in appearance. Half of the subjects and one of the leaders in each group received psilocybin. Without prior knowledge of the effects, the remaining subjects and the other leader received nicotinic acid, a vitamin which causes transient feelings of warmth and tingling of the skin, in order to maximize suggestion for the control group.

Data were collected during the experiment and at various times up to six months afterwards. On the experimental day tape recordings were made both of individual reactions immediately after the religious service and of the group discussions which followed. Each subject wrote an account of his experience as soon after the experiment as was convenient. Within a week all subjects had completed a 147-item questionnaire which had been designed to measure phenomena of the typology of mysticism on a qualitative, numerical scale. The results of this questionnaire were used as the basis for a one-and-one-half-hour, tape-recorded interview which immediately followed. Six months later each subject was interviewed again after completion of follow-up questionnaire in three parts with a similar scale. Part I was open-ended; the participant was asked to list any changes which he felt were a result of his Good Friday experience and to rate the degree of benefit or harm of each change. Part II (52 items) was a condensed and somewhat more explicit repetition of items from the post-drug questionnaire, Part III (93 items) was designed to measure both positive and negative attitudinal and behavioral changes which had lasted for six months and were due to the experience. The individual, descriptive accounts and Part I of the follow-up questionnaire were content analyzed with a qualitative, numerical scale by judges who were independent from the experiment.

Prior to the experiment the twenty subjects had been matched into ten pairs on the basis of data from the pre-drug questionnaires, interviews, and psychological tests. Past religious experience, religious background, and general psychological make-up were used for the pairings in that order of importance. The experiment was designed so that one subject from each pair received psilocybin and one received the control substance, nicotinic acid. This division into an experimental and control group was for the purpose of statistical evaluation of the scores from each of the three methods of measurements which used a numerical scale: the post-drug questionnaire, the follow-up questionnaire, and the content analysis of the written accounts.

The data from these three methods of measurement were presented by categories. The individual items which were used to measure each category were listed in groups for each method. The difference in score between each of the ten pairs of experimental and control subjects were analyzed statistically by the Sign Test for each item and also for the total scores of items in groups. In addition, examples of each of the nine categories were given in the form of excerpts from the descriptions which were written by the subjects.

From these data the conclusion was drawn that under the conditions of our experiment, those subjects who received psilocybin experienced phenomena which were apparently indistinguishable from, if not identical with, certain categories defined by our typology of mysticism. When analyzed statistically, the scores of the experimental subjects were significantly higher than those of the control subjects form all three methods of measurement in all categories except sense of sacredness. In all the other eight categories there were less that two chances in one hundred that the difference was due only to chance rather than to psilocybin, and in more than half the categories less than two chances in one thousand. Even sacredness showed a statistically significant difference in score (chance expectation of no more than five chances in one hundred) from both questionnaires, but not from the content analysis. The degree of completeness or intensity of the various categories was presented and discussed by comparing the consistency of score levels on individual items and groups of items among the three methods of measurement. Not all categories were experienced in the most complete way possible, although there was evidence that each category had been experienced to some degree.

In terms of our typology of mysticism, ideally the most "complete" mystical experience should have demonstrated the phenomena of all the categories in a maximal way. The evidence (particularly from the content analysis and also supported by impressions from the interviews) showed that such perfect completeness in all categories was not experienced by the experimental subjects. The phenomena of internal unity, however, were experienced to a rather complete degree; and because unity is the heart of the mystical experience, phenomena of the other categories might also have been expected to have been experienced to just as complete a degree as "by-products". In our data such a prediction was correct for transcendence of time and space, transiency, paradoxicality, and persisting positive changes in attitude and behavior toward self and life. The evidence indicated a less, although almost, complete experience of external unity, objectivity and reality, joy, and alleged ineffability. There was a relatively greater lack of completeness for sense of sacredness, love, and persisting positive changes in attitude and behavior toward others and toward the experience. Each of these last eight categories or subcategories was termed incomplete to a more or less degree for the experimentals, but was definitely present to some extent when compared with the controls. When analyzed most rigorously and measured against all possible categories of the typology of mysticism, the experience of the experimental subjects was considered incomplete in this strictest sense. Usually such incompleteness was caused by results of the content analyses.

The control subjects did not experience much phenomena of the mystical typology and even then only to a low degree of completeness. The phenomena for which the scores of the controls were closest to (although still always less than) the experimentals were: blessedness and peace, sense of sacredness, love, and persisting positive changes in attitude and behavior toward others and toward the experience.

The design of the experiment suggested an explanation for the experience of these phenomena at all by the controls. The meaningful religious setting of the experiment would have been expected to have encouraged a response of blessedness, peace, and sacredness. In the case of sacredness, implicit phenomena such as awe, wonder, mysterious fascination in spite of terror or fear, and sense of the wholly otherness of what was met in the experience showed a statistically significant score difference in favor of the experimentals compared to the controls, whereas phenomena with a more explicit indication of sacredness by the use of conventional religious or theological terminology did not show a significant difference between the two groups. In the case of love and persisting changes toward others and toward the experience, observation by the controls of the profound experience of the experimentals and interaction between the two groups on an interpersonal level appeared from both post-experimental interviews to have been the main basis for the controls' experience of these phenomena.

The experience of the experimental subjects was certainly more like mystical experience than that of the controls who had the same expectation and suggestion from the preparation and setting. The most striking difference between the experimentals and controls was the ingestion of thirty milligrams of psilocybin, which it was concluded was the facilitating agent responsible for the difference in phenomena experienced. This conclusion gave support to the claims made by others who have used psilocybin or similar drugs such as LSD or mescaline to aid in the induction of experiences which are concluded to be not unlike those described by mystics. Such evidence also pointed to the possible importance of biochemical changes which might occur in so-called "non-artificial" mystical experience (especially the effects of ascetic practices).

After and admittedly short follow-up period of only six months, life-enhancing and -enriching effects similar to some of those claimed by mystics were shown by the higher scores of the experimental subjects when compared to the controls. In addition, after four hours of follow-up interviews with each subject, the experimenter was left with the overwhelming impression that the experience had made a profound impact (especially in terms of religious feeling and thinking) on the lives of eight out of ten of the subjects who had been given psilocybin. Although the psilocybin experience was quite unique and different from the "ordinary" reality of their everyday lives, these subjects felt that this experience had motivated them to appreciate more deeply the meaning of their lives, to gain more depth and authenticity in ordinary living, and to rethink their philosophies of life and values. The data did not suggest that any "ultimate" reality was no longer important or meaningful. The fact that the experience took place in the context of a worship service with the use of symbols which were familiar and meaningful to the participants appeared to provide a useful framework within which to derive meaning and integration from the experience, both at the time and later.

The relationship and relative importance of psychological preparation, setting, and drug were important questions raised by our results. A meaningful religious preparation, expectation, and environment appeared to be conducive to positive drug experiences although the precise qualitative and quantitative role of each factor was not determined. For example, everything possible was done to maximize suggestion, but suggestion alone cannot account for the results because of the different experience of the control group. The hypothesis that suggestibility was heightened by psilocybin could not be ruled out on the basis of our experiment. An effort was made to avoid suggesting the phenomena of the typology of mysticism, and the service itself made no such direct suggestion. Psychologists of religion by their interest in psychology and presumed religious sensitivity should be well qualified to study the variables at work here.

Mention was made of the elucidating suggestiveness of our experimental findings for a better psychological understanding of the theological significance of worship and of such doctrines as the efficacy of the sacraments, the Incarnation, the Holy Spirit, the presence of Christ, and *gratia activa*. Questions were raised as to the place of the emotional factor compared to the cognitive in religious worship and as to the validity of mystical experience in terms of religious truth.

The demonstration of at least psilocybin, if not LSD and mescaline by analogy, as a tool for the study of the mystical state of consciousness suggested both further research and implications for the future. Possibilities for research in the psychology of religion with these chemicals were divided into two different kinds in relation to the aim: (1) theoretical understanding of the phenomena and psychology of mysticism and (2) experimental investigation of possible social application in a religious context.

The method suggested for the first or theoretical kind was to approach the mystical state of consciousness as closely as possible under experimental conditions and to measure the effect of variables. Suggestions were given for confirmatory studies of the work already done, additional new experiments, and better techniques of measurement. This dissertation was only a start toward this approach for a better understanding of mysticism form a physiological, biochemical, and psychological perspective.

Several experimental approaches were envisioned for the second kind of research to determine the best method for useful application in a religious context. One suggestion was the establishment of a pilot research center on the model of a religious retreat where carefully controlled drug experiments could be done by a trained research staff which would consist of psychiatrists, clinical psychologists, and ministers. Another suggestion was a study of the effect on small natural groups of four to six people who would meet periodically, both prior to and after a drug experience, for serious personal and religious discussions, Bible study, and worship in the form of prayer and meditation.

It was emphasized, however, that more research is needed at the theoretical level before such pilot research projects should be started because confirmation is first required that personally and socially useful changes in attitude and behavior are facilitated through the administration of these drugs with a meaningful religious preparation and setting. Care and caution were stressed because of the social resistance to be overcome and, most importantly, because of potential dangers involved.

Although relatively rare and not evident in our experimental results, possible harmful effects of the drug experience were discussed, such as, psychological dependence, apathy toward productive work and accomplishment, and suicide or prolonged psychosis in depressed or unstable individuals who would not be able to manage the intense emotional discharge. Research to minimize such dangers was suggested.

With full recognition of the caution and sensitivity which would be required, great promise was seen for future research in this complex and challenging area of the psychology of religion. A plea was made, however, for a serious and thoughtful examination of the sociological, ethical, and theological implications while research on the primary or theoretical level is progressing and before projects for testing useful social application in a religious context become widespread.

Chapter I
INTRODUCTION

Psychology of religion has always been interested in religious experience, and especially such intense forms as conversion and mysticism. Research has had to depend mostly on autobiographical accounts long after the fact. There have been few truly empirical studies which have analyzed these phenomena during or shortly after they have occurred.

With increasing frequency, books and articles have been appearing which make the claim that certain chemical substances (most notably mescaline, lysergic acid diethylamide, and psilocybin) are capable of inducing under appropriate conditions "mystical" or "religious" experience. Such claims have been met with skepticism from many religious people, and rightly so. The evidence presented has been, in most cases, a series of very subjective personal accounts which, while interesting, does not systematically attack the problem or prove the point.

In the first place, "mystical" or "religious" experience is to broad and general a term; it lacks precise definition as to what exactly is meant. One cannot be sure that any two persons are talking about the same thing unless the phenomena are first carefully defined. In the second place, personal accounts and subjective claims do not prove anything without controlled studies to rule out the possibility that these experiences were due to factors other than drugs. Also, such experiences usually occur under a variety of conditions and circumstances in which the number of unknown factors is so complex as to defy differentiation and elucidation. In the third place, an enthusiastic claim made by a person who has had the experience is open to the suspicion of misguided personal bias in the interpretation of what actually occurred.

This investigation was undertaken, therefore, to study in an empirical way the similarities and differences between experiences described by mystics and those induced by these drugs. The research was designed to overcome the three shortcomings which were mentioned above.

(1) A phenomenological typology of the mystical state of consciousness was carefully defined after a study of the writings of the mystics themselves and of scholars who have tried to characterize mystical experience.

(2) Some drug experiences were empirically studied not by collecting such experiences wherever an interesting or striking one might have been found and analyzed after he fact, but by conducting a double-blind, controlled experiment with subjects whose religious background and experience as well as personality were evaluated *before* their drug experiences. The preparation of the subjects the setting under which the drug was administered, and the collection of data about the experiences, were made as uniform as possible.

(3) The experimenter himself conducted the experiment, collected the data, and wrote up the results without ever having had an experience with any of these drugs. Furthermore, the typology by which the drug experiences were measured was constructed before the drug experiment was run.

Before proceeding with a presentation of our typology of mysticism and our experimental evidence, we shall briefly review the historical use of naturally occurring psychedelic[1] substances used in connection with religious practice as well as the literature on so-called "mystical" or "religious" experiences produced by synthetic psychedelic chemicals.

---

1. "Psychedelic" was coined by Dr. Humprey Osmond from the Greek and, literally translated, means "mind-manifesting" or "mind-opening" ("A review of the clinical effects of psychotomimetic agents," *Annals of the New York Academy of Sciences*, Vol. LXVI, [1957], pp. 418-434.) These substances produce changes in the mental state with the retention of mental clarity and awareness. Mescaline, psilocybin, and lysergic diethylamide (or, more simply, LSD) are the best known. Other terms which have been used are: "psychotomimetic," "hallucinogenic," "illusionogenic," "mind-distorting," etc. Although such effects may also occur, these words imply a negative evaluation, whereas the phenomena herein studied were generally regarded positively by those who experienced them.

Chapter II
RELIGION AND PSYCHEDELIC SUBSTANCES: A SURVEY

Data from History, Archaeology, Anthropology, Botany, and Psychopharmacology

Evidence from archaeology and anthropology has indicated that certain plants have been used in connection with rituals and religious ceremonies in the past; and there are groups of people who still employ them for such purposes in order to induce unusual states of consciousness. In some instances, such naturally-occurring substances are taken by a priest, shaman, or witch doctor to induce a trance for divinatory or revelatory purposes; sometimes they are taken by groups of people who are participating in sacred ceremonies.[1] Many of these plants have been found to contain compounds identical with, or closely related to, mescaline, LSD, or psilocybin.[2] From this evidence, some of which he has helped to discover, and from personal experience as a participant observer in certain of these ceremonies, R. Gordon Wasson has proposed the hypothesis that the use of such plants was an important factor in the origin of religious ideas among primitive peoples.[3]

No one knows when "mescal buttons," the spineless heads of the small, gray-green cactus, *Lophophora williamsii*, first began to be used by the Indians of Mexico. But when the Conquistadores arrived, they found that the Aztecs regarded peyote as a sacred plant and used it for ritual dances and curing ceremonies.[4] Some sources indicate that peyote was known and used as a religious sacrament as far back as 300 B.C.[5] The ritual and medicinal use of peyote spread northward to the United States sometime between 1700 and 1880, but there is no agreement as to whether this was by slow diffusion or because of knowledge gained while northern tribes were on warring expeditions into Mexico.[6]

Peyotism in Mexico, with its shamanistic emphasis on curing and divination, tribal dancing, and close association with agriculture and hunting, is compared and contrasted in detail by La Barre with the Mescalero or transitional peyotism of the Southwest and with Plains peyotism.[7] According to Slotkin, by 1885 "the tribal dancing rite had been changed into the form of a religion-like rite of singing, prayer, and quiet contemplation. ... both as a symbol of the spirits being worshiped and as a sacrament."[8] This peyotism of the Plains Indian spread farther northward from tribe to tribe by active proselytization all the way to Canada. The "Peyote Religion" of the Native American Church, which was officially founded in Oklahoma in 1918, has followed the form of Plains peyotism, which combines traditional Indian ritual and symbology with some Christian elements.[9]

The ceremony itself has some important features in common among different groups. The rite is an all-night affair from about 8:00 p.m. on Saturday until about 8:00 a.m. on Sunday. Four or five Indian officials lead the rite which usually takes place in a tipi with a fire in the center. The time is spent in prayer; songs by each participant in turn, accompanied by the water drum; ingestion of the sacramental peyote; and contemplation.

The ritual follows a definite general pattern, but the contents of the individual prayers and songs are spontaneous. At midnight there is a water-drinking ceremony and at dawn, after a ritual "baptism" with water from the drum, a ceremonial breakfast of water, parched corn in sweetened water, fruit, and dried sweetened meat, is eaten.[10]

The ceremony is regarded as very sacred by the participants who feel that peyote aids contemplation by increasing the powers of introspection, sensitizing the conscience, and producing visions of great meaning. Preparation for the rite is taken seriously by the Indians who conduct themselves with due solemnity throughout the ceremony.

Proper ritual behavior includes being physically clean; spiritually pure; and psychologically humble, sincere, and in a mood for concentrated meditation.[11]

White men who have attended these worship services and eaten peyote with the Indians in a receptive way as participant-observers, have confirmed the serious and sacred nature of the ceremony. "I had respect for the ceremony. It was reverent and well conducted."[12] "On a number of occasions, I have taken peyote in Indian ceremonies in Oklahoma, and I must say that I am impressed with the reverence and seriousness of the Indian in the practice of the peyote ceremony, the moral teachings of which are of the highest."[13] "I have never been in any white man's house of worship where there is either as much religious feeling or decorum."[14]

Peyote has been found to contain mescaline and seven other anhalonium alkaloids of the isoquinoline series. One of mescaline's notable effects is the production of richly colored visual imagery.[15]

Another plant used for religious purposes by the Aztecs was called *ololiuqui* and has been identified as the climbing morning glory, *Rivea corymbosa*. The brown seeds were crushed and eaten, usually by an individual rather than by a group, as an aid in divination for lost objects or diagnose and treat disease. The effect was the production of revelatory visions. *Ololiuqui* was held in great veneration and was considered a powerful force in native religious philosophy. The seeds were thought to possess a deity and therefore were called "divine food." These seeds are still used in a sacred way by the Chinantec, Mazatec, Mixtec, and Zapotec Indians of Oaxaca Province.[16]

Badoh negro, the black seeds of another morning glory, *Ipomoea violacea*, have recently been discovered to have a similar ceremonial use in some parts of the Zapotec country.[17]

Both *ololiuqui* and *badoh negro* seeds have been found to contain the same three derivatives of LSD-25 (*d*-lysergic acid diethylamide): (1) *d*-lysergic acid amide, (2) *d*-isolysergic acid amide, and (3) chanoclavine. Of these derivatives, *d*-lysergic acid amide has the most similarity in psychic effects to LSD, but is much weaker on an equivalent-weight basis.[18]

The practice of a sacred-mushroom cult has survived in three parts of the world: Northeastern New Guinea, the mountains of Oaxaca Province in Mexico, and Western Siberia.[19] Not much is known about the New Guinea cultic use, but research is in progress.

The sacred mushrooms of Mexico were called *teonanacatl*, "flesh of the gods," by the Aztecs. In 1939 Schultes presented evidence from historical, anthropological, and botanical sources for the existence of such cultic rites.[20] Johnson and his party were the first modern white people to observe, but not participate in, the sacred ceremony, which has survived in Mexico from before the Spanish conquest until the present.[21] In 1957 the Wassons presented a review of all the previous evidence along with their own discoveries. They argued that the pre-Columbian "mushroom stones" which had been found in the highlands of Guatemala really were meant to represent mushrooms as a symbol of the center of a sacred cult. The earliest of these artifacts have been dated about 1500 B.C.[22]

The ceremony itself has been described in detail (with pictures) by the Wassons, who were the first outsiders to partake of the sacred mushrooms in the secret rite, which took place at night and combined ancient Indian religious tradition with some Roman Catholic symbols. The mushrooms are used in different ways in different places in the remote mountains of Oaxaca, but they are always considered sacred and used with solemnity and seriousness. The Wassons have testified in their account to the profound impression which the various ceremonies in which they have participated have made upon them.[23]

Roger Heim, Director of the National Museum of Natural History in Paris, collaborated with the Wassons on later expeditions and classified most of the different sacred mushrooms as species of *Psilocybe*.[24] Hofmann identified and named the active ingredients as psilocybin and psilocin and was later able to synthesize both.[25]

The mushroom ceremonies of the tribes of Western Siberia, in the area of Kamchatka, have not been studied in so great detail as those of the Mexican Indians. It is clear, however, that the *Amanita muscaria* has been used for centuries by shamans prior to ceremonial rituals, to induce oracular and ecstatic trances. These mushrooms are also eaten in group ceremonies, the religious character of which is not so evident.[26] *Amanita muscaria* has been found to contain muscarine and slight traces of bufotenine, but no psilocybin. Although bufotenine in sufficient quantity can affect psychic functioning in a way somewhat resembling psilocybin, there is considerable doubt that there is enough in these mushrooms to account for the effects produced.[27]

Bufotenine has also been identified as an active ingredient of *cohoba* snuff of ancient Hispaniola, and is still used by Indian tribes. The seeds of several species of *Piptadenia*, a tree of South America and the Caribbean Islands, are pulverized and used as snuff to induce a trance-like state for prophesying, clairvoyance, and divination.[28] Also chemically present may be N,N-dimethyltryptamine, which is definitely responsible for the psychic activity of *vinho de Jurumena*, a drink made from the seeds of the closely related leguminose *Mimosa hostilis* and used in the magico-religious ceremonies of the Pancaru Indians in Pernambuco, Brazil.[29]

The Indians of the Western Amazon prepare a magic drink called *ayahuasca*, *caapi*, or *yaje* (equivalent designations), from several species of *Banisteriopsis*, a jungle creeper, or in some areas, *Tetrapterys methystica*.[30] This drink is used in religious manner, for prophecy, divination, the tribal initiation of male adolescents, and sacred feasts.[31]

There is still debate as to the exact nature of all the chemical compounds which are responsible for the pronounced psychic effects, but it seems very certain that harmine and its analogs, harmaline and *d*-tetrahydroharmine, are actively present.[32]

Bufotenine (5-hydroxydimethyltryptamine) and N,N-dimethyltryptamine are both closely related to psilocybin (4-phosphoryloxy-w-N,N-dimethyltryptamine). Harmine and LSD also contain the same basic indole ring structure. All these compounds have a structural relationship to serotonin (5-hydroxytryptamine) which is found in the brains of warm-blooded animals and which plays an as yet unknown role in psychic functioning.[33]

Data from Clinical Research

Once the active ingredients of these plants were isolated, their chemical structure determined, and a method of synthesis discovered, clinical research on their effects was facilitated. Mescaline was synthesized in 1920;[34] LSD in 1938 (although the mental effects were only discovered accidentally by Hofmann in 1943);[35] and psilocybin in 1958.[36] There was a surge of psychiatric interest on these drugs in the 1950's because many of their effects resembled psychotic symptoms. The drugs became known as "psychotomimetics."

Unger, in a comprehensive review article,[37] has shown how the possibility of rapid and positive personality change in contrast to the production of "model psychosis" began to be explored by some researchers who emphasized the importance of *extra*-drug variables in determining the type of reaction experienced by experimental subjects. These extra-drug factors included preparation and personality of the subject, a trust-filled setting in which the subject felt secure, and the expectation of both the subject and the experimenter. Unger has compared examples from William James' *Varieties of Religious Experience* with some of these experimentally-produced drug experiences.

Some of the researchers have reported that their subjects have tended to describe their drug experiences in mystico-religious language. A group of Canadian investigators, in their research on the treatment of alcoholics with LSD and mescaline, were struck by the resemblance of some of the drug experiences to religious conversions.[38] They also noted that the experiences which seemed to be the most therapeutic as measured by decrease in drinking were the ones which were the most intensely religious or transcendental in nature.[39] Sherwood *et al.*, using a similar method of preparation and administration, in their preliminary report, have described the results of these Canadian workers. Experiences which both the researchers and their subjects regarded as religious were encountered and also tended to be the most beneficial in terms of lasting therapeutic results. These experimenters classified such experiences in the "stage of immediate perception." The nature of the religious and philosophical insights reported by their patients were discussed in the appendix to their paper.[40]

Chandler and Hartman have mentioned the mythological, symbolic, religious, mystical and philosophical content of the experience of some of their subjects.[41]

Ditman and Whittlesey have recorded the rather numerous religious elements in questionnaire studies of their subjects after the experience. "Those who had a religious orientation, particularly those with a mystical orientation, claimed the most benefit from the experience and found it the most pleasant."[42]

Leary found that even subjects who had no formal interest in religion found religious language most adequate in describing their psilocybin experiences:

> We were dealing rather with the potentialities of expanded consciousness, the state of ego-suspension or self-transcendence. Such ancient concepts as faith, belief, trust, served as the best predictors.
> Another surprising result was the frequent use of religious terminology to explain the reactions. Less than ten percent of our original sample were orthodox believers or churchgoers, yet such terms as "God," "divine," "deep religious experience," "meeting the infinite," occurred in over half of the reports.[43]

Another clinical psychologist, Wilson Van Dusen, likened his LSD experience to the Zen Buddhist experience of *satori*, although his realizations were unexpected in the sense that he had not embarked upon the experience with such an expectation in mind.[44]

Persons already interested in religion or philosophy who have personally had a meaningful drug experience have been struck by the similarity of their experiences with those described by mystics and visionaries from a variety of cultures. Aldous Huxley opened the eyes of many to such a possibility when he described his first mescaline experience in *The Doors of Perception*.[45] Some of the others who have compared their experiences favorably to religious or mystical experience are Watts,[46] Heard,[47] Jordan,[48] Graves,[49] and Dunlap.[50]

Persons who have written in the field of the psychology of religion have been mixed in their reactions to drug-induced experiences as a method of approach to the study of religious or mystical experience. William James felt that in his own experiences with nitrous oxide, he approached closer than at any other time to a mystical state of consciousness. He was also extremely interested in the "anesthetic revelations" of others.[51] In general he judged all religious experiences more by the pragmatic "fruits for life," rather than by their origin, and therefore was open to the study of any phenomenon, regardless of its cause.[52] Stace has termed this "the principle of causal indifference"[53] and has himself included in his major work on mysticism a mescaline experience as a duly-qualifying example.[54]

[54] *Ibid.*, pp. 71-77.

Leuba had a chapter entitled "Mystical Ecstasy as Produced by Physical Means" in which he discussed the effects produced by alcohol, opium, hasheesh, and peyote, but he considered such experiences as lower forms of mysticism, and did not do any experimental work with these substances.[55] Laski[56] and Walker[57] discuss the issue, but tend to be more interested in, and favorable toward, "natural" experiences than "artificial." Zaehner, referred to in footnote 45, regarded such induced states as much nearer to psychotic than religious experience, and argued for the difference rather than similarity to Christian mysticism. Havens has presented a thoughtful and conservatively favorable review of the problem in relation to the religious experience of Quakers.[58] Clark has suggested the opportunities and challenges which such a research tool provides for future work in a relatively unexplored area in the psychology of religion.[59]

Chapter III
THE DEFINITION OF MYSTICISM

The purpose of this chapter is to define what we meant by the term, mystical state of consciousness. A typology of basic characteristics of mystical experience in the broad sense is developed. The broad sense means a basic typology which is universal and holds true for mystical experience in different cultures and religions. Before defining the typology in detail, we shall discuss mystical experience with regard both to its relationship to religious experience and to the universality of its occurrence.

Mystical Experience in General

The Relationship between Mystical Experience and Religious Experience

A simple identification of religious experience and mystical experience fails to take into account the many definitions of religion. Religions vary in their emphasis upon mysticism, although there is a tendency, especially among psychologists of religion who have been interested in the dramatic and intense phenomena of the mystical experience, to make the mystical element the most important characteristic of religion.[1]

All religious experience is not necessarily mystical in the sense of our definition of mystical experience as given below. Pratt, for example, divides religion into four kinds or aspects, of which the mystical is only one, the other three being the traditional, the rational, and the practical or moral.[2] Even when quite emotionally meaningful, participation in a particular religion by such practices as observance of religious laws, intellectual belief in a certain creed or theology, institutional membership, and attendance at rites and rituals, may not result in or be the product of mystical experience.

On the other hand, all mystical experience is not necessarily religious. Again, of course, much depends on how one chooses to define religion. If one makes the concept of a "personal God" central in the definition of religion, many forms of mystical experience could not be considered religious. The phenomena of mystical experience, for example, may occur outside the framework of any formal religion, with no reference to any articulated theology.

The problem is by-passed or merely indicated, rather than solved, by broadening the definition of religion to include any experience which would qualify as mystical by our criteria. Tillich, for example, considers as religious an experience which gives ultimate meaning, structure, and aim to human experience or in which one is concerned ultimately.[3] Wach gives a similar definition of religious experience as a total and intense existential response to what is experienced as Ultimate Reality (i.e., nothing finite) and adds the practical criterion that the experience must compel to action.[4]

Rather than attempting to define religion and religious experience in order to differentiate precisely the relationship between religious and mystical experience, we have indicated the nature of the problem and the error of loosely speaking of religious and mystical experience as if the two were always synonymous.

---

1. William James reflects this attitude by his preference for religion which is an "acute fever" rather than a "dull habit" (*op. cit.*, p. 8).
2. J.B. Pratt, *The Religious Consciousness: A Psychological Study* (New York: Macmillan, 1921), p. 14. Compare a similar discussion of the elements of religion by R. M. Thouless, *An Introduction to the Psychology of Religion* (Cambridge: Cambridge University Press, 1956), pp. 12-15. Pratt includes all four divisions in his definition of religion, which is as follows: "the serious and social attitude of individuals or communities toward the power or powers which they conceive as having ultimate control over their interests or destinies" (*op. cit.*, p. 2). Note Thouless's similar definition of religion: "a felt practical relationship with what is believed in as a superhuman being or beings" which are "felt to be greater than man or may be looked up to by him" (*op. cit.*, p. 4).
3. Paul Tillich, *Systematic Theology* (Chicago: University of Chicago Press, 1951), Vol. I, pp. 11-14. It is Tillich's opinion that what is truly ultimate can be best symbolized by Jesus who is called the Christ, in Christian theology (pp. 15-18).
4. Joachim Wach, *The Comparative Study of Religions*, (Columbia Paperback Edition; New York: Columbia University Press, 1961), pp. 30-36. See also his important work, *Types of Religious Experience: Christian and Non-Christian* (Chicago: The University of Chicago Press, 1951), pp. 32-33.

Our attention will be focused upon the nature of the mystical experience, whether the experience be religious or not.

The Universality of the Characteristics of Mystical Experience

Many of the well-known commentators on and analysts of mystical experience have made the presupposition that there are certain fundamental characteristics of the experience itself which are universal and are not restricted to any particular religion or culture, although particular cultural, historical and religious conditions may influence both the understanding and the description of the essential mystical experience.

James lists four common or universal characteristics of mystical experience: (1) ineffability, or the feeling that the experience cannot adequately be expressed with words; (2) noetic quality, or the certainty that the knowledge gained as insight is true; (3) transiency, or the impermanence of the mystical state; (4) passivity, or the feeling that one is not acting but, rather, being acted upon.[5] His examples range from persons with no particular religious allegiance to minks and nuns, but the cases in his series possess these common characteristics. Pratt provides a broad and universal definition of mysticism as a consciousness of Beyond, or the sense or feeling of the presence of a being or reality, via other means than sense perception or reason.[6] He distinguishes between mild and extreme types. The mild is characterized by (1) ineffability, (2) noetic certainty, especially of the presence of the Beyond, and (3) joy and calm.[7] The extreme type is exemplified by the unitive state of ecstasy which includes the phenomena of (1) suddenness, (2) passivity, (3) loss of sense impressions of the outside world, (4) noetic insight or knowledge or acquaintance which combines feeling and cognitive intuition, (5) ineffability, (6) immediate intuition of the Beyond, or God's presence, and (7) intense, ecstatic joy and love.[8] He takes his examples from both Eastern and Western sources.

Bucke has collected cases from various times and cultures with the following universal criteria of cosmic consciousness": (1) suddenness or instantaneousness, (2) photism or subjective light, (3) moral elevation, with an emotion of joy, assurance, and triumph, (4) ineffable intellectual illumination, (5) sense of immortality, (6) loss of the fear of death, (7) loss of the sense of sin, (8) usual occurrence between the ages of 30-40, and (9) added charm to the personality after the experience.[9]

Underhill gives four universal tests which must be satisfied by any example of true mysticism and which penetrate behind the particular descriptive symbolism employed.[10] For her mysticism must: (1) be an organic life-process in which the whole self is involved in an active, practical, and intense experience (this in contrast to an intellectual opinion which can be merely passive and theoretical), (2) have a wholly transcendental and spiritual aim (i.e., the mystic is interested in a realm of ultimate reality, the changeless One, beyond ordinary, everyday reality); (3) know this One not merely as the Reality of all that is, but also as a living personal object of Love which draws one's whole being under the guidance of the heart - love is defined as the driving power and deep-seated desire of the soul toward its Source and is "the ultimate expression of the self's most vital tendencies";[11] (4) have a Living Union with this One involving the liberation of a new, or rather latent, form of consciousness which is called "ecstasy" or better, the Unitive State.

Clark also makes the assumption that there are universal characteristics of the mystical state of consciousness. He lists and comments upon those mentioned by James and Underhill and adds (1) that "the language of mysticism makes extensive use of figures of speech and paradox,"[12] (2) that the mystics "regard what the ordinary man considers the Real as the Unreal, and what the ordinary person considers the Unreal as the Real"[13] and (3) that the mystic has a "tendency toward extravagance in behavior" which expresses his "desire for integration of the psychic life."[14]

Johnson universally defines mystical experience as the state of illumination in which the sense of separateness, of individuality, is to a great degree lost and which has positive significance, value, and certainty for the experiencer.[15] Such experiences are divided into the slighter and the more profound types. He finds the following four common features of the slighter type:

> (a) The illumination or radiance which is seen to infuse everything 'without' is felt to come from 'within.' (b) The sense of belonging to a new and greater unity is always felt. That which is seen forms a part of a larger whole (c) The emotional tones are always supremely attractive: pulsing light, livingness, joy, peace, happy wonder. Through them, and interwoven, is an enormously enhanced sense of the supreme values, and the most adequate description usually seems to the experiencer to be a 'revelation of God.' (d) Words fail to express the experience, and the terms used are known to be only symbols and analogies.[16]

He lists the universal features of the more profound type in two groups:

> 1. Those who have had the more profound type of mystical experiences, no matter in what age or to what race or creed they have belonged, tell us the *same* fundamental things: the sense of separateness vanishes into an all-embracing unity, there is certain knowledge of immortality, there is an enormously enhanced appreciation of values, and there is knowledge that at the heart of the universe is Joy and Beauty. This unanimity of testimony is quite remarkable.
> 2. Those who have known such an experience are always profoundly impressed by its significance as a revelation of truth. There is from then onwards, not the satisfaction of an intellectual answer to life's ultimate questions, but a serenity born of the knowledge that all is well, and that the secret purpose of the universe is good beyond all telling.[17]

Johnson quotes experiences which are described in traditional religious language as well as those which do not mention orthodox religious symbols yet still have the universal phenomenology covered by his description.
Walker considers the mystical consciousness a state of Universal Consciousness which is a higher level than the usual self-consciousness of everyday existence. Characteristics include an intuitive, experiential realization that "the small individual self has *always* been a part of the great Universal Self," a "melting away of the individual 'self' into 'boundless being'"[18] and "a world completely *outside* of time."[19] His chief examples are Edward Carpenter, Wordsworth, Sri Aurobindo, R. M. Bucke, Jacob Boehme, H. G. Wells, Plotinus, Meister Eckhart, and his own personal experience. His quote from Ouspensky demonstrates his own presupposition and that of the other writers mentioned above:

> If we follow neither the religious nor the scientific views, but try to compare descriptions of the mystical experiences of people of entirely different races, of different periods and of different religions, we shall find a striking resemblance amongst these descriptions, which can in no case be explained by similarity of preparation, or by any resemblances in ways of thinking and feeling. In mystical states, utterly different people, in utterly different conditions, *learn* one and the same thing, and what is still more striking, in mystical states there is no difference of religion. All the experiences are absolutely identical: the differences can be only in the language and in the form of discipline.[20]

[18] Walker, *op. cit.*, p. 40.
[19] *Ibid.*, p. 41.
[20] *Ibid.*, pp. 92-93, quoting from P. D. Ouspensky, *A New Model of the Universe* (London: Routledge & Kegan Paul, 1937), p. 51.

Although Suzuki doesn not make the claim that the *satori* experience is the same as other mystical states of consciousness, his description has many of the same universal characteristics given by other writers on mysticism: (1) irrationality which defies intellectualization, conceptualization, or logical explanation, (2) intuitive insight, (3) authoritativeness or finality, (4) affirmation or positive acceptance of all things that exist, (5) sense of the beyond or a melting away into something indescribable and of quite a different order than that to which one is accustomed, (6) impersonal tone, (7) feeling of exaltation, (8) momentariness - abruptness and transitoriness.[21]

W. T. Stace in *Mysticism and Philosophy* has surveyed the mystical literature to make his case for the universality of the basic phenomena of mystical experience. He has given examples from the writings of those who have personally experienced mystical states of consciousness to support what he calls the universal core of mystical experience. He has distinguished between introvertive and extrovertive types which both "culminate in perception of, and union with, a Unity or One though this end is reached through different means in the two cases."[22] He has listed seven characteristics of each type but five of the seven are the same. These five common elements are:

1. Sense of objectivity or reality, (comparable to James' noetic quality which leads to certainty of the objective reality of what is learned in the experience).
2. Feelings of blessedness, joy, peace, happiness, satisfaction, etc.
3. Feeling that what is apprehended is holy, divine, and sacred.
4. Paradoxicality.
5. Alleged by mystics to be ineffable.[23]

The introvertive type as the name suggests is inner-directed and its essence is the experience of undifferentiated unity which is "... the Unitary Consciousness, from which all the multiplicity of sensuous or conceptual or other empirical content has been excluded, so that there remains only a void and empty unity."[24] The Unitary Consciousness is by definition nonspatial and nontemporal. The extrovertive type is outer-directed and is experienced through the physical senses in or through the multiplicity of objects. The essential characteristic for this type is "... the unifying vision expressed abstractly by the formula 'All is One.'" The One is apprehended "... as being an inner subjectivity in all things, described variously as life, or consciousness, or a living Presence."[25] Spatiality is paradoxically preserved, but the normal sense of time may be lost.

The extrovertive and introvertive are not mutually exclusive and may occur in the same mystic.[26] Stace shows how Meister Eckhart is an example of this.[27] Brinton's study of Jacob Boehme supports Stace's point. Boehme harmonized the in-going and out-going wills by going from one goal to the other and back in a kind of dynamic equilibrium.[28] Stace maintains that although the extrovertive and the introvertive One are experienced in different ways, they are identical.[29]

Primary Experience versus Interpretation

After a general discussion of the problem of the universal core Stace quotes the writings of representative mystics from a wide variety of cultures to substantiate the extrovertive and introvertive types and each of them common characteristics. He always tries to reach behind individual interpretations which he feels are conditioned by various theological and intellectual frames of reference, to the raw experience itself. Again and again he emphasizes his distinction between primary phenomenology and interpretations conditioned by culture. He feels that his characteristics of the universal core are the basic phenomenology of mystical experience stripped bare of interpretation.[30]

[29] *Ibid.*, p. 152, 273-274.

Stace's distinction between the primary experience and the interpretation is either stated or implied by other writers who attempt to abstract general characteristics of the mystical experience from the phenomenological accounts thereof. Some examples are as follows:

> Such symbolism as this - a living symbolism of experience and action, as well as of statement - seems almost essential to mystical expression. The mind must employ some device of the kind if its transcendental perceptions - wholly unrelated as they are to the phenomena with which intellect is able to deal - are ever to be grasped by the surface consciousness. Sometimes the symbol and the perception which it represents become fused in that consciousness, and the mystic's experience then presents itself to him as 'visions' or 'voices' which we must look upon as the garment he has himself provided to veil that Reality upon which no man may look and live. The nature of this garment will be largely conditioned by his temperament - as in Rolle's evident bias toward music, St. Catherine of Genoa's leaning toward the abstract conceptions of fire and light - and also by his theological education and environment. Cases in point are the highly dogmatic visions and auditions of St. Gertrude, Suso, St. Catherine of Siena, the Blessed Angel of Foligno; above all of St. Teresa, whose marvellous self-analyses provide the classic account of these attempts of the mind to translate transcendental intuitions into concepts with which it can deal. (underlinings mine)[31]
>
> We must however, be careful to distinguish between the content of the intuition which takes place during the ecstasy, and the truths which the mystic comes to believe as a result of reflecting upon his experience.[32]
>
> I recognize the fact that those who have enjoyed mystical experiences are likely to describe them afterwards in terms of their own religion, and that this entails their making use of the terminology and the beliefs of the religion in which they happen to have been brought up.[33]
>
> This mystical experience, in its essential aspects as *experience*, is pretty much the same through the centuries and in all lands. What accounts for the historical *types* is, there fore, not the nature of the experience as such is, therefore, not the nature of the experience as such, but the prevailing theological or metaphysical conceptions of the time and place, which color the *expectation* of the given mystic, and form the background setting through which he interprets his illumination.[34]
>
> The fact is that the mystical feeling of enlargement, union, and emancipation has no specific intellectual content whatever of its own. It is capable of forming matrimonial alliances with material furnished by the most diverse philosophies and theologies, provided only they can find a place in their framework for its peculiar emotional mood.[35]
> As far as the psychology of satori is considered, a sense of the Beyond is all we can say about it; to call this the Beyond, the Absolute, or God, or a Person is to go further than the experience itself and to plunge into a theology or metaphysics.[36]

It is recognized that not all writers on mysticism accept the presupposition that mystical experience has a universal core which is basically the same but which is interpreted differently according to time, place, personality, and culture. We are not speaking of Rudolph Otto who in *Mysticism, East and West* might seem to

take the position that mysticism is *not* fundamentally one and the same, and therefore, that the essence of the experience is not independent of circumstances and conditions. For example, he says:

> It is still very generally held that mysticism, however diverse the sources from which it springs is fundamentally one and the same, and as such is beyond time and space, independent of circumstances and conditions. But this seems to me to contradict the facts. Rather, I hold that, in spite of the similarity of terms, which can be surprising enough, there is a diversity in mystical experience which is not less than that of religious feeling in general.[37]

Diversity which he emphasizes here is the variety of expression or interpretation. For example: he distinguishes between the soul-mysticism of Yoga and Buddhism and the God-mysticism (mysticism of union) of Theism.[38] He points to subtle differences between Eckhart and Sankara in use of metaphors and ethical content reflected in doctrines of salvation, justification, sanctification, and grace as well as in valuating of the world.[39] He devotes the longest part of his discussion, however, to a comparison of their similarities, both in regard to their experiences and to their metaphysical speculations.

In terms of Stace's position, these differences are mainly differences of interpretation or intellectual expression rather than of the primary experience itself. In fact, Otto also makes this distinction when he gives the conclusions of his study:

> We maintain that in mysticism there are indeed strong primal impulses working in the human soul which as such are completely unaffected by differences of climate, of geographical position or of race. These show in their similarity an inner relationship of types of human experience and spiritual life which is truly astonishing. Secondly, we contend that it is false to maintain that mysticism is always and everywhere one and the same quantity. Rather, there are within mysticism many varieties of expression which are just as great as the variations in any other sphere of spiritual life, be it in religion generally, or in ethics or in art. (underlining mine)[40]

Many of Stace's categories are illustrated as basic to the experience of both Eckhart and Sankara even when Otto is trying to show their metaphysical differences. For example, the introvertive and extrovertive types are discussed by Otto as "the two ways: the mysticism of introspection and the mysticism of unifying vision" which interpenetrate and become one in both Sankara and Eckhart.[41] Both describe an experience of unity with a losing of self and a submergence into the absolute, unqualified, one divinity.[42] The category of objectivity and reality is illustrated by the discussion of their common intuitive mystical knowledge.[43] Both hold to a metaphysical theism which resulted from a personal experience of the holy, sacred, and divine.[44] Both give evidence of the experience of the exalted feeling of mystical, numinous rapture, although Otto feels that Eckhart also paradoxically emphasizes humility as result of the experience of numinous majesty.[45]

The Otto of *The Idea of the Holy* is closer to Stace's approach because here Otto describes the phenomenology of what he calls the "characteristic notes of mysticism in all its forms, however otherwise various in contents."[46] The universal features he lists are (1) annihilation of the self or rejection of the delusion of selfhood by means of a consciousness of the transcendent as the sole and entire reality[47] and (2) "Identification in different degrees of completeness, of the personal self with the transcendent Reality ... the Something that is at once supreme in power and reality and wholly non-rational."[48]

R. C. Zaehner clearly does not agree with Stace's argument for the universal core and in *Mysticism, Sacred and Profane* argues against such a view throughout.[49] Zaehner goes one step beyond Otto's analysis by stating: "But there is not only a difference in tone between Eckhart and Sankara, which Otto himself fully brough out; there is obviously a fundamental difference in the experiences which must have formed the basis of the two men's writings" (underlining mine).[50] In his analysis of mystical experience Zaehner distinguishes three types which he insists are quite distinct: (1) the pan-en-henic (all-in-one) experience found especially in nature mystics, (2) the Atman-Brahman union of the individual self with the Absolute (in this experience the phenomenal world is superceded), and (3) Christian theistic mystical union with God by love (in this experience the self remains a distinct entity.).[51]

Zaehner admits his own Roman Catholic bias.[52] He implies that Christian theistic mysticism at its best is true supernatural union with God, whereas the Atman-Brahman experience, although theistic, reaches only self-isolation in rest and emptiness within the self. For him the pan-en-henic experience is definitely inferior to either of the other two, because to admit that nature mysticism is a form o union with God would be pantheism and would identify God with the evil in nature.[53]

The pan-en-henic and Atman-Brahman types correspond to Stace's extrovertive and introvertive experiences of unity with the One, although he would maintain that the same One or Absolute was being experienced in both types.[54] Stace argues that the Atman-Brahman and Christian theistic types represent the same basic experience and that culture and individual conditioning account for the apparent differences.[55] Here again Stace insists that interpretation not be confused with the primary experience.

No one would deny that there are many varieties of expression and interpretations of mystical experience. This study is not an attempt to settle the debate as to whether there is a universal core of primary experience interpreted differently because of differences in cultural situation and individual conditioning or whether there are many varieties of expression and interpretation because different cultural situations and individual conditioning actually produce different experiences which have no universal, basic core of identity. The former position is taken as our presupposition on the basis of the work of Stace and the others mentioned above.

As a tool of evaluation for the empirical data from drug experiences, a typology of the phenomenology of mystical experience is developed below. Stace's position has been used as a presupposition in two ways. First, his list of the basic characteristics of the universal core of mystical experience has been used as a framework which has been enriched and expanded from other thinkers who have dealt with the same problem. Second, his distinction between primary experience and the interpretation of this experience points toward an ideal of phenomenological analysis. The reservation must be added that perhaps it is impossible ever to reach pure uninterpreted experience.

Phenomenological Typology of Mystical States of Consciousness

Category I: Unity

Category of unity is divided into internal and external types, which are different ways of experiencing and undifferentiated unity. The major difference is that internal unity is experienced through an "inner world" *within* the experiencer, and external unity is perceived with the senses through the external world *outside* the experiencer.[56] The experiences themselves are phenomenologically different. Both are experiences of unity and therefore are listed as subcategories.

Internal Unity

The essence of internal unity is the direct experience of an undifferentiated unity. This unity comes with the loss of the multiplicity of all particular sense impressions. There is a fading or melting away into pure awareness with no empirical distinctions or particular content except the awareness of the unity itself.[57] One is beyond the self-consciousness of sense impressions or empirical ego, yet one is not unconscious, but very much aware of the undifferentiated unity. There is a loss of the sense of finite selfhood and personal separate identity, but experience is not extinguished: it has its content the pure awareness of the empty, yet full and complete unity. During the experience there is a dissolution of individuality with no internal or external distinctions, yet the person is aware of the experience.[58] After the experience such a phenomenon can be remembered. Such a non-empirical, inner experience is by definition non-temporal and non-spatial.[59]

These phenomenological descriptions contain several paradoxes which Stace maintains are necessary in order to give as adequate a representation in words as is possible of an experience which the mystics allege to be ineffable. He calls the loss of the empirical ego with the retention of awareness of the unity one example.[60] The undifferentiated unity itself is called empty, yet full and complete; is considered both impersonal and personal; is experienced both as totally inactive, static, and motionless and as dynamic, creative, and active. Stace calls this the vacuum-plenum paradox referring to the negative and positive aspects respectively. These aspects are not mutually exclusive, but one side may be emphasized more than the other due to culture, personality, and intellectual frame of reference. Stace gives examples from representative mystics of the world.[61]

Such a discussion of paradox involves the question of interpretation. Interpretations are handles with which to get a hold on and deal with the experience conceptually. We are interested chiefly in the universal core of primary experience. Some mention, however, of the various interpretations which different mystics have used to integrate their experiences into their philosophies of life or theological frameworks is necessary in order to recognize the basic experience more easily.

According to Stace, the closest to the pure experience of internal unity with no interpretation added is the Hinayana Buddhist experience of Nirvana which is revealed and participated in when the stream of ordinary conscious states is gradually stopped. Nirvana "transcends both the individual consciousness and the space-time world."[62] Hinayana Buddhism stops with this experience of pure undifferentiated unity and makes no interpretation of what this experience is other than to call it Nirvana. The mystical traditions of all the other higher cultures go at least one step further and interpret this unity as the pure ego or the unity of the self. The Samkhya, Yoga, and Jaina philosophies stop here, but other cultures then push the interpretation and identify the pure undifferentiated unity which is reached after transcendence of the usual sense of self or empirical ego with something greater-than-self or all-encompassing.[63]

---

56. Internal and external unity correspond to Stace's introvertive unitary consciousness and extrovertive unifying vision, respectively (*op. cit.*, pp. 63-133.
57. Stace, *op. cit.*, pp. 86-87.
58. *Ibid.*, pp. 111-123, 245.
59. *Ibid.*, p. 110.
60. *Ibid.*, pp. 224-245.
61. *Ibid.*, pp. 163-178.
62. *Ibid.*, p. 127.
63. *Ibid.*, pp. 123-127.

Suzuki describes the *satori* or enlightenment experience of Zen Buddhism as a dissolution of the usual sense of individuality by melting "away into something indescribable, something which is of a quite different order from what I am accustomed to."[64] It is this something of a quite different order which has received many names. For example, for Tennyson, "individuality itself seemed to dissolve and fade away into boundless being." (underlying mine)[65] For Koestler, "the I ceases to exists because it has, by a kind of mental osmosis, established communication with, and been dissolved in the universal pool."[66] J. A. Symonds, the nineteenth century man of letters, called this underlying or essential consciousness "a pure absolute, abstract Self."[67] Plotinus described the state of simple unity as a merging with the Supreme or the One.[68] It is Stace's opinion that the Hinduism of the Upanishads and the advaita Vedanta identify the pure ego with the Universal or Cosmic Self (Brahman or the Absolute)[69] and that Mahayana Buddhism uses the concept of Sunyata or the pure Void for the same basic experience.[70]

According to Stace, orthodox Islam, Christianity and Judaism have emphasized the transcendence of God and condemned pantheism or identity with God as heresy. Their mystical traditions reflect this emphasis and regard the experience of unity as something less than identity with God.[71] In the Sufi mysticism of Islam, *fana* (passing away or melting away into the Infinite is correlative to baga, "which means the survival in God of the soul which has experience fana."[72] Orthodox Christian mysticism uses such terms as union with God, the Divine Unity, or spiritual marriage, but is careful to qualify such statements with the explanation that "the individual soul does not wholly pass away into God, but remains a distinct entity."[73] Stace regards Judaism as the least mystical of all the great world religions. Judaism insists on the greatest gulf between creature and Creator, yet does not rule out relationship between the individual and God. The Haisidic mystics are closest in phenomenological description to an experience of internal unity, but Stace does not consider them the major trend in Judaism.[74]

With the example of Martin Buber, the Jewish philosopher, we come back to the basic experience, free from interpretation.

> "Now from my own unforgettable experience I know well that there is a state in which the bonds of the personal nature of life seem to have fallen away and we experience an undivided unity." (underlining mine)[75]

Stace points out how Buber at first interpreted this experience as "union with the primal being or the God-head," but that later he repudiated this interpretation and chose to understand his experience as "the basic unity of my own soul ... certainly beyond the reach of all the multiplicity it has hitherto received from life ... though not in the least beyond individuation ... and not 'the soul of the All.'" Such a position shows similarities with Hinayana Buddhism in the basic phenomenology of the experience and the refusal to interpret the experience beyond the self. Buber's Jewish background may well be the reason for his repudiation of his initial interpretation, as Stace suggests, but his basic experience of undivided unity still remains.[76]

Various metaphorical expressions occur in descriptions of this state of internal unity and can be classified according to which side of the vacuum-plenum paradox they belong.

76. Stace, *op. cit.*, pp. 156-157, quoting from Buber, *op. cit.*, pp. 24-25.

The vacuum or negative side includes nouns as emptiness, darkness, nothingness, void, abyss, silence, stillness, nakedness, nudity, or desert; and such adjectives as contentless, imageless, numberless, formless, wayless, fathomless, soundless, spaceless, or timeless. The plenum or positive side includes such nouns as fullness, completeness, brightness, light, oneness, perfection, or pureness; and such adjectives as harmonious, infinite, limitless, or boundless. Both sides are needed to give a complete picture of the basic experience and sometimes they are paradoxically joined in the same metaphor.[77]

Other writers on mystical experience besides Stace have described the phenomena of internal unity as an important characteristic of the mystical state.

> The central aspect of it (genuine mystical experience) is the fusion of the self into a larger undifferentiated whole.[78]

Underhill says the following in her account of the state of mystical ecstasy:

> In this experience the departmental activities of thought and feeling, the consciousness of I-hood, of space and time - all that belongs to the World of Becoming and our own place therein - are suspended. The vitality which we are accustomed to split amongst these various things, is gathered up to form a state of 'pure apprehension': a vivid intuition of - or if you like conjunction with - the Transcendent.[79]
> Self-mergence, then - that state of transcendence in which ... the barriers of selfhood (are) abolished ... is the secret of ecstasy.[80]

Others do not give as precise a phenomenological description as Stace, but the similarity is apparent. Pratt describes the unity as a state of consciousness in which the outside world is shut out and the senses are closed.[81]

Johnson states that "the highest mystical experiences show that the Spirit of man, his true Self, lies beyond this (usual sense of selfhood) and is normally veiled from the Ego ... The essence of mysticism is the glimpsing of the true Self by the Ego." In the highest state when all the "veils" are stripped away, "there is complete blissful unity in the One, the Impersonal, the Absolute."[82] Walker's mention of "the melting away of the individual 'self' into 'boundless being'" (underlining mine) is similar to the passages quoted from Suzuki and Tennyson above.[83]

Stace classifies the experiences of Tennyson and Koestler (see quotes above) as incomplete examples of internal unity because they din not *completely* experience undifferentiated unity. There was not a total loss of extraneous sense impressions or complete certainty of the loss of individuality, and there fore, not truly *pure* awareness.[84] Such a distinction is an attempt to be very precise, but if some of the mystics which Stace uses as examples of the complete experience could have been questioned as Koestler was, perhaps their experiences, too, would have to be categorized as incomplete. However, this distinction between complete and incomplete can be used as a general guide when other statements which might be included under the subcategory of internal unity are examined. For example, the consciousness of "Beyond" as described by Pratt[85] and Clark[86] or the awareness of a "More" with which one's higher self is coterminous and continuous as discussed by James[87] is not alone sufficient for internal unity without also the loss of sense impressions and pure awareness.

86. Clark, *op. cit.*, p. 263.
87. James, *op. cit.*, pp. 498-499.

Although such phenomena are certainly very close to internal unity and can form a valid part of the complete experience, alone they are not enough. Similarly the boundaries of the personal self of usual experience may be partially broken down or dissolved within the self without complete loss of all distinctions and the emergence of pure awareness.

Also the kind of loss of sense of self which results in unconsciousness as in sleep or coma is not the same as the paradoxical dissolution of the self in internal unity. Without the phenomena which includes the essential experience of undifferentiated unity, these experiences are characteristic only of an incomplete form of internal unity.

In summary, there are both complete and incomplete forms of the basic introvertive experience of internal unity, and there are various metaphors and ways of interpretation. The essence of the experience stripped bare of all interpretation is a direct, conscious experience of undifferentiated unity in pure awareness when all sense impressions fade or melt away and the empirical ego is transcended.

The state then attained is called by various names in the major mystical traditions: Nirvana, the Void, the Pure Self, the Universal or Cosmic Self, the Absolute, the One, or union, bond, or contact with God. But here interpretation begins and basic phenomenological analysis ends.

External Unity

Unity may also be experienced through the physical senses as an underlying oneness behind the empirical multiplicity of the external world. The sense of oneness with external objects (inanimate or animate) is the essence of this subcategory. The observer or subject feels that the usual separation between himself and an object is no longer present, yet the subject still knows that his individuality is retained. In spite of the empirical multiplicity of objects, which are still perceived as separate, the subject-object dichotomy is nevertheless in a paradoxical sense dissolved. On one level the objects are separate, yet at the same time at another and more basic level they are one with the subject.[88] Another way of expressing this phenomenon is to say that the essences of objects are experienced intuitively while their outward forms are experienced through the senses. At the deepest level the essence or inner reality of all things is felt to be one.[89] The subject feels a sense of oneness with these objects, because he "sees" that at the most basic level all are a part of a single unity.[90] External unity may also present itself as a deeply felt awareness of the life or living presence in all things or as the realization that nothing is "really dead."[91] The unifying vision is experienced at an insightful rather than purely rational level through animate and/or inanimate "objects" external to the self. This profound feeling of oneness as an expression of the underlying undifferentiated unity despite empirical multiplicity is the criterion.

The most complete form of external unity has both depth and breadth. The deep oneness experienced through individual objects or people is felt to be part of the underlying unity in all things. Any experience without this cosmic dimension lacks maximum completeness.

The fully developed experience of external unity certainly includes an expansion of consciousness beyond the usual sense of self as well as a consciousness of a "Beyond" or "More" which in such a case may represent the unity. As in the instance of internal unity, however, these phenomena alone, without any relation to undifferentiated unity experienced through the external world of objects, are not enough to constitute external unity. At best they may be considered incomplete or undeveloped forms. They are necessary but not sufficient elements.

---

88. Stace, *op. cit.*, pp. 64-65.
89. *Ibid.*, pp. 69-70.
90. Walker, in describing the level of Universal Consciousness experienced by Edward Carpenter, states: "...we lose the customary feeling of existing as separate individuals and find ourselves, instead, a part of everything else ... the subject and object coalesce and become one." (*op. cit.*, p. 39.) Johnson phrases the same thought as "The sense that all the visible, tangible world is a part of a larger whole and is apprehended as having an underlying unity ..." (*op. cit.*, p. 326).
91. Stace *op. cit.*, p. 78. Bucke also describes such a living presence in his own experience of cosmic consciousness. (*Op. cit.*, p. 8.)

Stace expresses external unity abstractly by the formula, "all is One." He makes this kind of unity by the chief characteristic of the extrovertive type of mystical experience.[92] Underhill discusses the same kind of experience as the illuminated vision of the world or the pantheistic and external type of mysticism.[93] The claim is made in both the experiences of internal and external unity that a level of reality other than the ordinary is touched. Stace identifies this reality or unity as basically the same in both kinds although the unity is perceived in a different way. He feels that the "all is One" of external unity has the same "One" which is experienced during the state called internal unity.[94] Although Stace's argument is impressive, it is not crucial to our thesis.

Category II: Transcendence of Time and Space

This category refers to loss of the usual sense of time and space. Time means clock time, but may also be one's personal sense of his past, present, and future.[95] Transcendence of space means that a person loses his usual orientation as to where he is during the experience in terms of the usual three-dimensional perception of his environment. Experiences of timelessness and spacelessness may also be described as an experience of "eternity" or "infinity."

The experience of internal unity by definition includes transcendence of both time and space because of the loss of all empirical sense impressions. The experience of external unity may or may not include the transcendence of time, but space is paradoxically and only partially transcended because external objects seem both separate and yet not separate because of the feeling of underlying unity.

Category III: Deeply Felt Positive Mood

The most universal elements (and therefore, the ones which are most essential in the definition of this category) are joy, blessedness, and peace. Their unique character in relation to the mystical experience is that their intensity marks them as being at the highest levels of the human experience of these feelings and they are valued highly by the experiencers.[96] Joy may be of an exuberant or quiet nature and may include such feelings as exultation, rapture, ecstasy, bliss, delight, and/or happiness.[97] Peace is of the profound nature that "passeth understanding." Closely related to peace is blessedness which includes beatitude, satisfaction, and/or a sense of well-being. Tears may be associated with any of these feelings of positive mood because of the overpowering nature of the experience.[98] These feelings may be directly associated with the peak of the experience or occur during the "ecstatic afterglow" when the peak has passed, but its effects and memory are still quite vivid and intense.[99]

Love is also an element of deeply felt positive mood which has been mentioned by many students of mysticism, but love does not have the same universality as joy, blessedness, and peace.[100] One example of mystical love is the love which may rise to an indescribable intensity and tenderness.[101]

94. Stace, *op. cit.*, pp. 152, 273-274.
95. Walker in describing the experience of Universal Consciousness says: "...the words 'before' and 'after' seem to have lost all their former meaning for us, so that we appear to have been transported to a world completely *outside* of time." (*Op. cit.*, p. 41.)
96. Stace, *op. cit.*, p. 68. Pratt, *op. cit.*, pp. 351-352.
97. Underhill, *Mysticism*, p. 366.
98. Laski, *op. cit.*, pp. 85-86.
99. "This is the condition that I call the 'ecstatic afterglow' when, with returning consciousness, the realization, appreciation, and interpretation of the experience begins." Laski feels that especially calm, stillness, peace, and sense of well-being are likely to carry over into an "ecstatic afterglow." (*Ibid.*, pp. 85-86)
100. Stace does not include love as one of the "universal core" characteristics (*op. cit.*, pp. 68). Pratt suggests that the more personal that God is to the mystic, the more the sentiment of personal love is aroused (*op. cit.*, p. 349). The very mention of "God" is for Stace already an interpretation rather than a description of the basic psychological experience.
101. Underhill, *Mysticism*, pp. 425-428.

Love has an interrelation with several other categories. The love of God which is especially common in Christian mysticism is an obvious example of the experience of sacredness (see next category). Love in terms of Union with God is one way of interpreting the experience of internal unity.[102] External unity also may have a mood of love especially if the oneness is attained through people, who become a symbol of the oneness in all things. The deeply felt mood or feeling in this case is not necessarily interpreted as love of "God."

In summary, deeply felt positive mood is most universally expressed by joy, blessedness, and peace. Love is closely related and may also be present.

Category IV: Sense of Sacredness

This category comprises the sense of sacredness which is evoked by the mystical experience. The sacred is here defined broadly as that which a person feels to be of special value and capable of being profaned. The basic characteristic of sacredness is a non-rational, intuitive, hushed, palpitant response in the presence of inspiring realities. No religious "beliefs" need necessarily be involved even though a sense of reverence or a feeling that what is experienced is holy or divine may be included.[103]

As Rufus Jones points out, Rudolph Otto calls such a non-rational (yet deeply felt) response the consciousness of the "numinous" which uniquely transcends the finite or ordinary and moves one with awe and wonder.[104] Otto's phenomenological description includes feelings of awe (with the emphasis on uncanniness or numinous dread), profound humility before the overpowering majesty of what is felt to be holy, numinous energy or urgency, a sense of the wholly otherness of what is experienced, and mysterious fascination in spite of terror or fear in the sense of shaking or trembling in the innermost depths of one's being.[105] These characteristics which Otto mentions are sufficient, but not exclusively necessary conditions. If they are present they can lead to a feeling of sacredness; but such a feeling may be experienced in other ways as well.

Otto emphasizes the feelings of fear, creaturehood, finitude, and humility in his description of the response to the holy. However, the previously listed elements of joy, blessedness, peace, and love may be closely related to, but not identical with, the sense of sacredness.[106] Positive mood and unity may be the emphasis rather than fear and separation. Awe has two elements, wonder and fear, and contributes to both types of experience; wonder is an important part of one type, and fear predominates in the other. Both types give rise to the feeling that what is apprehended is sacred, and both may be present at different points in the same experience.

It might be argued that an exclusive experience of separation could not also include the experience of unity. Fear and creatureliness emphasize the negative side of the vacuum-plenum paradox. The full range of the mystical experience must take into consideration both negative and positive possibilities or a combination of the two sides.[107] An experience with no element of unity or no joy, blessedness, or peace would not be considered the most complete kind of mystical experience. (See the last section in this chapter for a further discussion of completeness.)

The expressions, "joy of the Lord" or "Love of God," which are used by Christian mystics show the close relationship between deeply felt mood and sacredness.[108] The phenomenology from the category of sacredness may be interpreted by the experiencer as an experience of "God," the presence of some other specific deity, or simply as a "sense of Presence."[109] Spontaneous acts of worship such as prayer or kneeling may be evoked. Otto argues that a profound existential experience of "creature-feeling" makes the experiencer strongly feel that the numinous is objective and outside the self.[110] Such a feeling is one possible example of the category of objectivity and reality which is to be defined and discussed next. However, an interpretation is involved if this something objective outside the self is identified as "God."

Category V: Objectivity and Reality

These category has two inter-related elements:

(1) insightful knowledge or illumination felt at an intuitive, non-rational level and gained by direct experience and
(2) the authoritativeness of the experience or the certainty that such knowledge is truly real, in contrast to the feeling that the experience is a subjective delusion. These two elements are connected because the knowledge through experience of ultimate reality (in the sense of being able to "know" and "see" what is really *real*) carries its own sense of certainty. The experience of "ultimate" reality is an awareness of another dimension not the same as "ordinary" reality which is the reality of usual, everyday consciousness, yet the knowledge of "ultimate" reality is quite real to the experiencer.

Such knowledge does not mean necessarily an increase in facts, but rather in insightful knowledge or intellectual illumination, e.g. seeing new relationships of old facts or ideas, new understandings of meanings, new appreciation of the universe as a whole, or an experience of "everything falling into place."[111] This immediate feeling of objective truth is called by James the noetic quality.[112] Things seen in a new light can become vital and living as never before.[113] Although the mystics do not dwell on personal psychological insights, Underhill has described an increase in self-understanding which comes from the mystical experience.[114] Such insight is also an example of intuitive knowledge which seems very real.

The lasting authoritativeness or conviction of the true reality of the experience and the sense of the profound significance of the content are at least closely related to, and perhaps enhanced by, the totality and intensity of the response. This knowledge at the level of intuition and insight is felt to require no proof at a rational level by the experiencer.[115] There is a feeling of being totally grasped and dealt with by ultimate reality. James calls this passivity.[116] The intensity and totalness is such as to leave no doubt to the experiencer of his participation at a very deep and basic level which although non-rational and even non-verbal is most convincing.[117] The unshakable certainty of the objective reality of the experience persists even after the experience is over. Stace discusses in detail the validity of the claim to objective reference, but we are concerned here only with the fact that the mystic is convinced of the objective reality of the experience of what to him is ultimate reality.[118]

Category VI: Paradoxicality

Rational statements about, descriptions of, and even interpretations of the mystical experience tend to be logically contradictory when strictly analyzed. Such paradoxical language is universally found in the writings of those who have had mystical states of consciousness when they try to describe their experiences.[119]

---

[111] Bucke describes such intellectual illumination in his definition of cosmic consciousness: "Like a flash there is presented to his consciousness a clear conception (a vision) in outline of the meaning and drift of the universe ... The person who passes through this experience will learn in the few minutes, or even moments, of its continuance more than in months or years of study, and he will learn much that no study ever taught or can teach. Especially does he obtain such a conception of THE WHOLE, or at least of an immense WHOLE, as dwarfs all conception, imagination or speculation, springing from and belonging to ordinary self consciousness, such a conception as makes the old attempts to mentally grasp the universe and its meaning petty and even ridiculous." (*Op. cit.*, p. 61).
Similar is his description of his own experience: "...it was impossible for him ever to forget what he at that time saw and knew, neither did he, or could he, ever doubt the truth of what was then presented to his mind." (*Ibid.*, p. 3.)

[112] James, *op. cit.*, pp. 331-332.

[113] Pratt, *op. cit.*, p. 411.

[114] *Mysticism*, pp. 375, 378.

[115] "There is no certitude to equal the mystic's certitude." (Underhill, *Mysticism*, p. 331.)

[116] "...the mystic feels as if his own will were in abeyance, and indeed sometimes as if he were grasped and held by a superior power." (James, *op. cit.*, p. 372.

[117] Pratt, *op. cit.*, pp. 347-48, 400-403.

[118] Stace, *op. cit.*, pp. 67-68, 134-206.

Examples of paradox have been mentioned in the typology above as a basic part of the mystical consciousness. In the experience of internal unity there is a loss of all empirical content in an *empty* unity which is at the same time *full* and complete. This loss includes the loss of the sense of self and dissolution of individuality, yet something individual remains to experience the unity. The "I" both exists and does not exist. External unity is experienced through the empirical multiplicity of the external world with the insight that all is One. There may also be a paradoxical transcendence of space.[120] The vacuum-plenum or negative-positive paradox has three aspects: the One or Universal Self is both unqualitied and qualitied, both impersonal and personal, and both inactive and active.

Category VII: Alleged Ineffability

The impossibility of adequate expression in words or unintelligibility of the mystical state of consciousness has been stressed as a main characteristic by writers on mysticism.[121] A distinction must be made between the time during the actual experience and afterwards. During the experience of either internal or external unity, there are no concepts or multiplicity to describe within the "unity" or the "One."[122] The profound intensity of positive mood accompanying the experience adds to the inadequacy of words to accurately communicate and tends to make one fall silent.[123] It would appear that there are grounds for the claim that during the experience, ineffability is a characteristic. But afterwards when they have had time to integrate and interpret, mystics have written descriptions of their remembered experiences while at the same time they have insisted that the actual experiences were indescribable.[124]

Stace gives an interesting psychological explanation for this alleged ineffability. Any experience, sensory or nonsensory, cannot be adequately communicated with words to a person who has not had the experience himself.[125] The unique and actual characteristic that mystics allege their experiences to be ineffable is based on an embarrassment with language. Statements made afterwards about the actual experience stripped of interpretation are literally true descriptions, but because mystical experience is paradoxical in nature, an attempt to be strictly logical involves contradiction. To avoid the frustration of contradiction, the mystic calls his experience ineffable.[126] The categories of ineffability and paradoxicality are thus closely related.[127] The category of objectivity and reality also has a close relationship to ineffability because the intuitive and insightful knowledge gained cannot be adequately communicated to others, although it remains of profound significance and reality to the experiencer.[128] Whether or not Stace's explanation is accepted, the alleged ineffability of mystical experience is a more accurate description of this category than simply "ineffability." If the actual experiences were truly beyond words, not much could be accomplished in a study of the mystical state of consciousness by a phenomenological analysis of even the remembered descriptions.

---

[119] James, *op. cit.*, pp. 408-412. Suzuki feels that persons who experience satori "are always at a loss to explain it coherently or logically." (*Op. cit.*, p. 103) Stace argues that mystical paradoxes are meant to be true paradoxes (i.e., both sides although contradictory are actually experienced and are not due to confusion or unclearness (*op. cit.*, pp. 257-276). The extensive use of figures of speech and paradox is one of Clark's characteristics of the mystical experience (*op. cit.*, pp. 273-74). Stace wold agree but would insist that much of what might at first be thought to be figure of speech or metaphor is in fact true description which is by nature paradoxical (*op. cit.*, pp. 299-303). This point is discussed further in the next section.

[120] Stace maintains that this paradox of identity in difference gives rise to pantheistic philosophical interpretations of mysticism. For example, the contradictory propositions that the world is identical with God and that the world is distinct from God are both asserted to be true (*op. cit.*, pp. 212-218ff).

[121] James, *op. cit.*, p. 371; Pratt, *op. cit.*, pp. 346-347, 476; Johnson, *op. cit.*, p. 325; Suzuki, *op. cit.*, p. 103.

[124] Stace, *op. cit.*, p 298.

[125] *Ibid.*, p. 283.

[126] *Ibid.*, pp. 304-306.

[127] Underhill, *Mysticism*, pp. 331-32. Suzuki uses the term "irrational" to cover both categories (*op. cit.*, p. 103).

[128] Pratt, *op. cit.*, p. 476.

Category VIII: Transiency

Transiency refers to duration and means the temporariness of the mystical state of consciousness in contrast to the relative permanence of the level of usual consciousness. Transient appearance of the special and unusual levels or dimensions of consciousness which are defined by this typology with subsequent disappearance and return to the more usual is the characteristic of this category. The peak level or climactic moment of the experience may last for only a relatively short period (variously described from seconds to hours) although the feelings of an "ecstatic afterglow" effect may be experienced for many hours or even days.[129] The characteristic of transiency, however, means that the mystical state of consciousness cannot be sustained indefinitely.

An objection might be raised at this point on the grounds that the greatest mystics achieved a permanent state of mystical consciousness which continued while they led active lives in the world.[130] Although continuing effects of the ecstatic afterglow can remain (but with decreasing intensity unless there are repeated mystical experiences) a prolongation of the peak experience of unitary consciousness or unifying vision could not have been sustained at the same level or lives of fruitful activity in the world would have been impossible.[131] With proper discipline for successful repetition of mystical experiences, a general change in level of consciousness may be induced, but this is not the same as a continual peak experience.[132] Such changes and other permanent effects of the experience in the experiencers' lives are considered in the last category below. The mystics' own descriptions of internal unity usually include references to transiency.[133] Similarly, the actual experience of external unity is not described as permanent.[134] Transiency is a characteristic of the immediate mystical state of consciousness which is felt by the experiencer to be on a different level or dimension from his usual state. The transient nature is realized by contrast when the experience is over.

Closely related to transiency is the suddenness of appearance and disappearance of these levels or dimensions of consciousness which are different from usual. The unexpected character of coming with an element of surprise no matter how well prepared one is or how hard one has tried to gain the experience enhances the sense of striking change from ordinary consciousness. Although Suzuki[135] combines both suddenness and transiency in the same category (listed as momentariness), we consider transiency the universal and most important of the two elements.

Category IX: Persisting Positive Changes in Attitude and/or Behavior

If a person goes through the kind of experience characterized by the eight categories above, his attitude and/or behavior are changed.[136] He cannot remain indifferent to the experience. The profound personal impact is a strong motivation for action, even if the result is only a rearrangement of the life in order to cultivate more mystical experience.[137] Positive effects of the mystical experience in the life and personality of the experiencer is the criterion of whether or not to call the experience truly mystical by many commentators and also by mystics themselves.[138] Such a value judgment, as well as the fact that the phenomena observed extend over a longer time that just the few minutes or hours when the primary experience occurred, makes this category stand apart from the preceding eight. However, the "fruits for life" or "value for life" is included in the typology with this acknowledgment in order to distinguish the experience as defined above from an experience which might resemble the typology but result in negative effects in the individual's life. Quietism and unhealthy self-indulgence are examples of this possible potentiality for effects in a negative direction.[139] We seek a typology of a healthful, life-enhancing mysticism, and thus, the present category describes positive effects.

---

[129] Laski, *op. cit.*, pp. 60-66. James, p. 372.

[130] See Underhill's discussion of the "unitive life" (*Mysticism*, pp. 413-44) or Pratt's chapter on "The Mystic Life" (*op. cit.*, pp. 430-441.

[131] Pratt speaks of the rhythm between contemplation and activity (*ibid.*, p. 433).

[132] Underhill states that "the greatest of the contemplatives have been unable to sustain the brilliance of this awful vision for more than a little while." (*Mysticism*, p. 331.).

[133] C. Butler in his *Western Mysticism* (Grey Arrow Edition; London: Arrow Books, 1960) includes transiency as a characteristic in his description of mysticism and gives specific examples from the writings of St. Augustine (pp. 165-167), St. Gregory the Great (pp. 140-141), and St. Bernard of Clairvoux (pp. 165-167).

[134] For example, Jacob Boehme's experiences as related in Brinton's biographical chapter were temporary although the impact and insight gained were so great as to have a lasting influence on his life. (Howard H. Brinton, *The Mystic Will* [New York: Macmillan, 1930], pp. 47-52)
Bucke's own experience of cosmic consciousness happened only once. "The illumination itself continued not more than a few moments, but its effects proved ineffaceable; ...There was no return that night or at any other time of the experience." (*Op. cit.*, pp. 7-8.

[135] *Op. cit.*, p. 108.

[136] Johnson, *op. cit.*, p.332. Clark, *op. cit.*, pp. 274-275.

[137] Compare this necessity for action to Wach's fourth universal characteristic of genuine religious experience - that it results in action. He distinguishes, however, the "right" action from any action. (Wach, *Comparative Study of Religions*, pp. 36-37).

These effects can be divided into four main groups of persisting changes in behavior and/or attitude: (1) toward self, (2) toward others, (3) toward life, and (4) toward the mystical experience itself. The duration of the change must also be considered. Diminishing afterglow effects may persist for days or even weeks, but usually fade away in time unless the experience is repeated. Changes which remain even after the experience is only a memory are the most significant.

(1) Increased integration of personality is the basic inward change in the personal self. This may come about as a fruit of a radical experience of death and rebirth or conversion; or from the profound depth of the experience, insight may be gained which can subsequently be utilized in a gradual reorganization of the personality and growth in maturity. Undesirable traits may be faced in a way that enables them to be dealt with and finally reduced or eliminated. Issuing from personal integration, the sense of one's inner authority may be strengthened, and the vigor and dynamic quality of a person's life may be increased. Creativity and greater achievement efficiency may be released. There may be an inner optimistic tone with consequent increase in feelings of happiness, joy and peace.[140]

(2) Attitudes and behavior toward others may change in such ways as more sensitivity, more tolerance, more real love.[141] The effectiveness of such change is measured by the response in others who may remark on the development of a more positive relationship, or have the tone of their lives changed. Another result of increased personal integration may be to be more authentic as a person by being more open and more one's true self with others.

(3) The third area of change is in attitude toward life and what one works for in life. One's philosophy in life, sense of values, sense of meaning, and purpose in life may be changed.[142] Vocational commitment may be strengthened or changed completely. The need to serve others may be felt. As a result of the experience of a new dimension in life, more appreciation for life and the whole of creation, a stronger sense of the preciousness of life, or an increased sense of reverence may emerge in a new way.[143] More time may be spent in devotional life and meditation.

(4) The experience itself is regarded as valuable and what has been learned is thought to be useful.[144] A positive experience is remembered as a high point, and an attempt may be made to recapture the experience or, if possible, to gain new experiences as a source of growth and inspiration. However, the experience is seen neither as a means to and end nor as an end it itself, but as a balance of both.[145] Mystical experiences of others

---

[138] James uses such a pragmatic approach as a guide in evaluating all kinds of religious experience (*op. cit.*, pp. 21-22, 321). Pratt also judges the value for life by the practical fruits (*op. cit.*, pp. 466-477). Zaehner points to Ruysbroeck's condemnation of quietism on the basis of what it produced (*Mysticism, Sacred and Profane*, pp. 173-174).

[139] H. N. Wieman and R. Westcott-Wieman, *Normative Psychology of Religion* (New York: Crowell, 1935), pp. 186-188.

[140] Such positive changes toward self are emphasized in discussions by Jones, the Wiemans, and Underhill. R. Jones especially notes the optimistic tone and heightened dynamic quality in the life of a person who has been opened to the utilization of resources of vital energy through transcendent experience (*The Inner Life*, pp. 171, 180). The Wiemans give a balanced presentation of both the potential evils and values of mystical experience. (*op. cit.*, pp. 186-91). Underhill is one of the most enthusiastic describers of the life-enhancing power of mysticism. (*Mysticism*, pp. 413-46; *Essentials of Mysticism*, pp. 12-14.)

[141] Underhill, *Mysticism*, p. 437.

[142] Clark stresses extravagance in behavior, (i.e., acting in an imprudent way for self-benefit) as a characteristic effect of mystical experience, (*op. cit.*, pp. 274-275).

[143] Wieman and Westcott-Wieman, *op. cit.*, pp. 190-191.

[144] Walker, *op. cit.*, p. 156.

[145] Stace, *op. cit.*, pp. 339-340.

are more appreciated and understood although even among mystics theological, philosophical, or cultural bias can lead to value judgments of preference for their own particular interpretations.

The Continuum of Mystical Experiences

Many writers on mysticism have noted a difference in degree in the experience. For example, Pratt distinguishes mild and extreme types of mystical experience.[146] Johnson divides his fifteen examples into three groups ranging from the slighter to the more profound.[147] Stace regards the extrovertive type of experience as on a lower level than the introvertive.[148] Thouless and Underhill differentiate various stages in the growth of the mystic life on a continuum from the prayer of quiet in which the self is awakened and illuminated to the ecstasy and spiritual marriage or unitive life.[149]

The categories in the above typology allow for e difference in intensity or level within the mystical experience. The question arises as to when an experience ceases to be defined as mystical. Stace has classified experiences which do not have all the core characteristics of either the introvertive or extrovertive types as atypical or borderline.[150] Laski in her study of what she calls transcendent ecstasy includes aesthetic experiences in art, poetry, music, drama, and nature; creative experiences in writing or scientific work; and certain sexual and childbirth experiences as well as the commonly termed religious or mystical experiences. Some of her criteria are the same as our categories, but the breadth of her characteristics leads her to include experiences in which all our categories would not be represented.[151] Such experiences would be called more or less atypical or borderline by our definition unless some essential characteristics from all of our categories were present. Some categories have a variety of phenomena which are an expression of the same universal characteristics. Not all the phenomena of each category need be experienced for the category to be counted positively in the evaluation of a particular experience (e.g., all the various elements of deeply positive mood or changes in attitude and behavior). What is experienced however, should occur to a strong or adequate degree to qualify that particular category when the completeness of the mystical typology as a whole is judged.

The category of unity is the most important, and if either external or internal unity is experienced, characteristics from the other categories are likely to be experienced also.[152] If neither internal nor external unity is complete, unity has not been truly experienced. Even if all the other categories are represented, such an experience must be considered as close to, but not strictly the same as the most complete mystical experience by our definition. In such a case, the total experience would be classified as incomplete, although more complete than atypical or borderline.

All the phenomena which resemble and include mystical experience[153] can be placed on a continuum from dim aesthetic feelings in nature and the arts through experiences considered as atypical or borderline to the complete extrovertive type and finally to the most profound introvertive experience with the strongest presence of characteristics in each of our categories.[154] The ideal example of the most complete mystical state would be an experience in which all categories were experienced to the strongest or most complete degree. With the suggested continuum in mind, this categorization of mystical states of consciousness can now be used to evaluate drug experiences and determine where on the continuum, if at all, they fit.

Chapter IV
EXPERIMENTAL DESIGN

The purpose of the experiment in which psychedelic drugs were administered in a religious context was to gather empirical data about the state of consciousness experienced. These data form the basis for a comparison with the typology of the mystical state of consciousness which has been presented above. Tape recordings, written accounts, questionnaires, and personal interviews were used to collect the data.

Non-drug Factors

Although descriptions in the psychopharmacological literature of the effects of these substances (LSD, mescaline and psilocybin) vary from "model psychosis" to "transcendental experience", investigators seem to agree that an alteration in the usual state of consciousness is produced. Researchers who report "transcendental" experiences in their subjects claim that set and setting are important factors.[1] Set is defined as the personal expectation, mood, mental attitude and past experience of the subject; setting is the external environment and atmosphere and includes the expectations of the investigator. Trust and confidence in both the administrator and the situation are emphasized as crucial. In this view, the drug is seen as the necessary means by which this kind of potential experience may be actualized in a person who is properly handled and prepared.

The kinds of experiences reported by those who have studied the use of these substances in religious ceremonies seem to support this theory.[2] Both the setting and psychological expectation are conducive to an experience of great positive significance for the participant. The participant knows what the procedure of the ceremony will be, and feels at ease as part of a group which undergoes the experience together.

The effects of set and setting were planned to maximize the possibility that mystical phenomena would occur. The assumption was made that for experiences most useful for comparison with the typology of mysticism, the atmosphere should be broadly comparable to that achieved by tribes who actually use natural psychedelic substances in religious ceremonies. The particular content and procedure of the ceremony had to be made applicable (i.e. familiar and meaningful) for the participants. Attitude toward the experience, both before and during, was taken into serious consideration in the experimental design. Preparation was meant to maximize positive expectation, trust, confidence, and reduction of fear. Setting was planned to utilize this preparation through group support and rapport, friendship, an open and trusting atmosphere, and previous acquaintance with the procedure of the experiment in order to eliminate, if possible, feelings of manipulation which might arise. The physical environment was a private chapel. There, on Good Friday, a two-and-one-half-hour religious service which consisted of organ music, four solos, readings, prayers, and personal meditation was attended by twenty Christian theological students, some of whom had taken psilocybin prior to the service.

Choice of Drug

Psilocybin was chosen because its duration of action is only four to five hours, compared to eight to ten for LSD and ten to twelve for mescaline, in doses equivalent in potency. The practical problem of the time needed

---

1. For a general statement of this position see T. Leary's article, "How to Change Behavior," in *Clinical Psychology*, ed. G.S. Nielsen (Proceedings of the XIV International Congress of Applied Psychology, Vol. IV; Copenhagen: Munksgaard, 1962), pp. 62-64. A more detailed account of the application and implications of this approach from the work of Leary's group is given by R. Metzner, G. Litwin, and G. Weil in *The Relation of Expectation and Setting to Experience with Psilocybin: A Questionnaire Study* (Dittoed by Harvard University Department of Social Relations) pp. 1-30. The method pioneered by A.M. Hubbard and used by the Canadian investigators, N. Chwelos, D.B. Blewett, C.M. Smith, A. Hoffer, H. Osmond, J.R. MacLean, D.C. MacDonald and U.P. Byrne, is explained in detail in Chwelos and Blewett's *Handbook for the Therapeutic Use of Lysergic Acid Diethylamide 25* (to be published), pp. 15-48. Sherwood, Stolaroff, and Harman have come to similar conclusions (*op. cit.*, p. 69).
2. As was mentioned in Chapter II, the following have been participant-observers in Indian ceremonies in which sacred mushrooms or peyote were eaten: Wasson and Wasson (*op. cit.*, pp. 287-316, Slotkin (*Tomorrow Magazine* Vol. IV, No. 3, pp. 64-70), and Osmond (*Tomorrow Magazine*, Vol. IX, No. 2, pp. 105-125).

to supervise experimental subjects dictated that the use of psilocybin was more feasible. Claims of various differences in the effects of these three drugs have not been conclusively demonstrated, e.g., greater color and visual imagery with mescaline, or more unpleasant reactions with LSD.[3] Any apparent advantage of psilocybin in terms of less preoccupation with imagery or generally more pleasant reaction is perhaps because psilocybin is newer and has not yet been researched as thoroughly. Also, because of the greater potency per unit weight of LSD, comparisons are not always between dosage effects of equivalent potencies. Higher doses of the same drug usually produce more intense effects, whether positive or negative. The oral dosage of psilocybin used was 30 mg. This dosage corresponds roughly to 150-200 micrograms of LSD or 500-750 mg of mescaline. The controls received 200 mg of nicotinic acid in identical capsules. This control substance produces transient vasodilation of blood vessels in the skin, especially of the face, and general relaxation.[4] This was used to potentiate suggestion in the control subjects, all of whom knew that psilocybin produced various somatic effects, but none of whom had ever had psilocybin or any related substance before the experiment.

Recruitment and Pre-testing of Subjects

Subjects were student volunteers from a local theological seminary. They were recruited through a lecture on rehabilitation-experiments in which psilocybin was given to convicts at the Concord State Prison. Those students who wanted a personal experience with psilocybin met with the experimenter. At this meeting it was explained that psilocybin would be administered during a private Good Friday worship service, and questions were answered about possible harmful effects and risks involved in taking an experimental drug. An effort was made not to overemphasize negative effects such as fear and psychotic-like symptoms which might produce a negative set. The California Psychological Inventory (CPI) as well as a medical-history form[5] and a pre-drug questionnaire[6] was completed by all volunteers. The medical history form was similar to that used by the Harvard University Health Services for screening volunteers for the Harvard Psilocybin Project (sponsored by the Center for Research in Personality).

The pre-drug questionnaire was designed by the experimenter to assess personal religious background, training, and experience in a predominantly open-ended way. Questions included church affiliation, theological position, conversion experience, mystical or other religious experience, and devotional life. During the following week, each volunteer participated in a two-hour interview with the experimenter. During this time the medical history was reviewed with further questioning on any positive item which had been mentioned. Particular note was taken of metabolic diseases; previous consumption of drugs, alcohol, and tobacco; seizures; family and personal history of mental illness and psychotherapy; and symptoms of hysteria. Each person was asked to interpret the meaning of the proverb, "A rolling stone gathers no moss," in order to check on fundamental abstract reasoning power. A physical exam was given to evaluate general physical condition and to provide a baseline in case any physical complaints developed after the experiment. Suggestibility was tested by having the person stand with his eyes closed and imagine that a strong wind was pushing him backwards. This test was also a measure of the degree of resistance or cooperation with the experimenter.

Conditions which would have been grounds for rejection of a volunteer were cardiac impairment sufficient to limit exercise or contraindicate emotional strain, liver enlargement or history of liver disease (e.g. hepatitis or jaundice), history of psychosis, present psychological imbalance (especially depression), or current intensive psychotherapy or analysis for severe psychological problems. No volunteer needed to be rejected on these grounds.

---

3. Unger summarizes the evidence (*op. cit.*, pp. 2-3 of his manuscript copy). The similarity between LSD and mescaline is stated by P. Hoch, H. Pennes, J. Cattell, *Chemical Concepts of Psychosis*, ed. M. Rinkel (New York: McDowell, 1958), p. 143. H. Isbell found similar effects produced by LSD and psilocybin ("Comparison of the reactions induced by psilocybin and LSD-25 in man," *Psychopharmacologia*, Vol. I 1959, p. 37). He also reported cross-tolerance which indicates the probability of a common pathway for LSD and psilocybin (H. Isbell et al., "Cross-tolerance between LSD and psilocybin," *Psychopharmacologia*, Vol. II 1961, pp. 147-159.
4. L.S. Goodman and A. Gilman, *The pharmacological Basis of Therapeutics* (New York: Macmillan, 1955), p. 1701.
5. See appendix A for a sample of the medical-history form.
6. See appendix B for a sample of the pre-drug questionnaire.

After the physical exam and review of the medical history, the pre-drug questionnaire was used as a guide in discussing the person's religious background and, especially, experience. Most of this time was spent in eliciting a description of the most meaningful religious experiences in the person's life. Care was taken not to suggest the basic phenomenology of the mystical experience to the subject, but rather to let him talk about his own experiences which he had mentioned in his questionnaire.

Preparation and Grouping of Subjects

Each person was given a written summary of the planned procedure of events on Good Friday and of the cooperation which was expected from him in collecting data during the days following. These points were discussed and questions answered. Suggestions were made for preparation by self-examination in depth, meditation, private devotional life, or reading of literature deeply meaningful to the person. These were suggestions only, and each person was told to prepare in the way which suited him best, but every effort was made to have him prepare, in as serious a manner as possible, for a meaningful experience.

When all the interviews had been completed, the data on each person were reviewed. Notes had been taken during each interview, and afterwards a general impression of the person had been written by the experimenter.

Related data from the questionnaire supplemented by the interview were combined into categories which were scored with a 0-5 rating scale made relevant to each category. The categories fell into three main divisions: 1) Past religious experience, 2) Religious background and training, 3) General psychological makeup. Ratings on the categories in these groups, the CPI scores, and the interviewer's general impression of each person were used to match the twenty volunteers into ten pairs. (For a more detailed description of the data used in matching, and how the 0-5 scale was adapted to each category, see the next chapter).

The twenty subjects were also divided into five groups of four persons each, on the basis of friendship and compatibility. Most of the subjects were in the same classes, ate together, and lived in the two dormitories which were next to each other on the campus. Groups were constituted without reference to matched pairs. There were only two different groups in which a pair of subjects were together. Each group was assigned two leaders who met with the group before the experiment.

These leaders were familiar with the effects and potentialities of psilocybin through personal experience and observation of others in group sessions of the Harvard Psilocybin Project. Each of the five leaders with the most experience worked in a group with another leader who had not had quite as much experience in helping people through the experience. The two leaders who worked together knew each other and felt compatible working as a team. They knew from past experience the positive and negative possibilities of the drug experience, and their very presence was a reassuring factor to the subjects. The chief purpose of these leaders was to aid in creating a friendly and trust-filled set and setting which, it was hoped, would maximize the potential for positive experience, and to manage with confidence any disturbing reactions which might occur. There was one leader far each subject who received psilocybin.

The experimenter held a briefing meeting with the leaders. Each leader received a printed summary of hist purpose and functions, and a protocol of the experimental procedure. Stress was placed on a supportive but non-directive role so that each subject's experience could have its own development. The leaders were purposely not told the characteristics of the typology of mysticism and were not shown the post-drug questionnaire or any of the data already collected on the subjects. Neither the leader nor the experimenter knew which subject would receive psilocybin. The experimental procedure was discussed in detail so that the leaders could be of maximal help in making the experiment run smoothly. Emphasis was placed on creation of an atmosphere which would not create feelings of manipulation, suspicion, or psychotic terror in the subjects. Strategies for handling such disturbing reactions were reviewed (e.g., taking the subject out of the chapel and reassuring him). Leaders were instructed not to interfere unless a subject was having obvious difficulty. Group assignments were made, and the procedure and purpose of the group meetings to be held by the leaders with their groups before the experiment were discussed.

Each group of subjects met with its two leaders for two hours on one occasion two to five days before Good Friday. The meeting was held in the dormitory room of one of the group members. The purpose of this meeting was to develop group spirit and to prepare subjects for as positive and meaningful an experience as possible. Group members had an opportunity to become acquainted and feel at ease with their leaders. Subjects were encouraged to let themselves go into unexplored realms of experience during the actual experiment and not to try to fight the effects of the drug, even if the experience became very unusual or frightening. The method of reaction to the experience was suggested, rather than specific content either positive or negative. The point was made that each person's drug experience was to be uniquely his own and could not be predicated with accuracy at the present state of knowledge. Possible physical symptoms such as nausea and vomiting were discussed as unwanted side effects which could be minimized or not experienced at all if the subjects were reassured that they were in good hands and that the experience, no matter how unusual, would be temporary. Personal preparation and the plan of the day on Good Friday were reviewed and discussed so that everyone was clear on the expected procedure. Subjects were instructed to eat an early, very light, non-fat breakfast. Each group selected its own meeting place on campus for the morning of the experiment.

Experimental Procedure

Drug Preparation

Double-blind technique was employed. The subjects had been told that some of them would receive psilocybin and some would be controls, but they did not know, that two of the subjects in each group would receive psilocybin, nor that the other two members, as controls, would receive a control substance, nicotinic acid. They had been told that one of their two leaders would receive a small dose of psilocybin. This was meant to add to the reassurance of the subjects and to aid group spirit and rapport with the leaders. Each pair of leaders knew that one of them and two of their group would receive psilocybin, but they were not told the nature of the control substance. Thirty capsules which were identical in outward appearance were prepared, eight hours before the experiment. Ten contained 30 mg of psilocybin; five contained 15 mg of psilocybin; and fifteen contained 200 mg of nicotinic acid. Powdered sugar was used to fill any unused space in the capsules. Each capsule was sealed in an unmarked envelope, and the envelopes were kept in three groups, according to contents.

The list of paired subjects was given to a helper who did not participate in the experiment and did not know any of the subjects or leaders. He flipped a coin for each pair to designate which would be experimental and which would be control. He then checked the group lists to make sure that the experimental and control subjects were divided evenly in each group. In one instance, the coin-flip determination was arbitrarily changed to maintain this balance. A similar procedure was followed for the five pairs of leaders. The helper then wrote the names on the appropriate envelopes, and the coding key was sealed in an envelope and locked in a drawer.

Protocol During the Experimental Day

The actual experiment in which psilocybin was administered to half of the participants occupied most of the day on Good Friday. A church in Boston provided exclusive use of a small prayer chapel which was connected by a hallway to three adjoining rooms in the basement. This chapel was large enough for fifty people. Two of the rooms were large, and the other was considerably smaller, but large enough to accommodate easily a group of six persons. The rooms were comfortably furnished with sofas and chairs. The "live" Good Friday service in the main sanctuary of the church upstairs was transmitted through a high-fidelity amplifier to speakers in the private chapel and two large rooms. Lighting in the chapel was controlled by a rheostat which was set for dim light. Candles were lit on the altar on either side of a golden cross. There were three stained-glass windows behind the altar. No incense was used. Exits from the experimental area were locked, except for one which could not be. A helper who was a clergyman was stationed there throughout the experiment to keep all participants in the experimental area and to prevent any persons not connected with the experiment from entering. Signs were placed on the outside of all other exits to indicate that a private worship service was in progress.

On the morning of the experiment, the two leaders met the four members of their group at their own predetermined meeting place at about 9:30 AM and went as a group by automobile to the church. By 10:05

AM, all groups had assembled in the church basement. Separate areas were assigned to each of the five groups so that one group met in each end of the two large rooms, and the fifth group in the smaller room. Participants helped to arrange the sofas and chairs into small circles with a tape recorder in the middle of each area. An opportunity was given for each person to become familiar with the physical surroundings of the experimental area, it.e., the chapel, the three rooms opening off the hallway, and the toilet facilities which also were entered from the hall. A brief meeting was held for everyone in one of the large rooms and to enable all student participants to meet the other group leaders whom they had not seen before. The minister who was to "stand guard" at the unlocked entrance was introduced and his function explained. The participants were encouraged to stay together in the chapel for the entire service, but were given the freedom to leave if they had to go to the toilet or if they felt restless. The understanding was made clear that everyone was to stay in the experimental area during the course of the day. An effort was made to allay any fearful tension and to encourage serious expectancy.

After this meeting, each group of four student volunteers and two leaders sat together in their assigned area. Shortly thereafter, at 10:30 AM, the envelopes were distributed to the group by the experimenter who watched as the capsules were swallowed with a small amount of water. For the next eighty minutes until it was time to move into the chapel, silence was observed in each group. Each individual was free to read, meditate or pray. The leaders were ready to help anyone who became frightened or experienced disturbing physical symptoms.

At 11:45 AM, a bell was sounded as the pre-arranged signal for all the group to move into the chapel. Each group sat together with their leaders. The minister welcomed everyone in the chapel before he went upstairs to start the service. An organ prelude was heard before the actual service started.

The experimenter remained outside the chapel in the hall to be of assistance in case of emergencies. Oral and injectible thorazine were available as well as other standard emergency drugs. A written record was taken of the subjects and leader who left the service from time to time to go to the toilet or to one of the other rooms. One of the large rooms was reserved for subjects who wanted to talk and the other for those who wanted to sit in silence. Each person who came out of the service was encouraged but not coerced to return. Most of the subjects remained in the chapel for the entire service.

At 2:30 PM when the service was over, the groups remained in the chapel. One leader went with one subject at a time back to the original group area where each subject described his experience into a tape recorder. After recording, each subject was escorted back to his group in the chapel. The other leader stayed with the group in the chapel during the recording.

At about 3 PM, after all the recordings were made, each group assembled in its area for a discussion and sharing of the experience. Fruit and juice were provided. All this conversation was recorded on tape.

By 4:30 PM, all subjects were judged recovered enough to leave. Each group was dismissed as a unit, and went out to eat together. After the meal, the leaders took each person home.

Collection of Data after the Experiment

The next morning, each subject called the experimenter to report his physical and psychological condition and how he had slept. Mental alertness and clarity, and presence or absence of headache, nausea, or dizziness were specifically elicited. The schedule of post-session interviews was arranged at this time.

In the days following the experiment, each subject wrote a description of his experience and mailed it to the experimenter. During the two-hour post-session interview, a 147-item questionnaire[7] was completed by each participant in about 30 minutes before any discussion. Certain items were based on the categories of the typology of mystical experience. Other items measured physical symptoms or unpleasant reactions such as fear, terror, anxiety, loneliness, depression, or hatred. The person was asked to evaluate the degree to which he experienced each item on a scale from 0-4:

---

[7] See appendix C for a sample of this post-drug questionnaire.

0 - None, or not experienced at all.
1 - Experienced so slightly as to be doubtful.
2 - Experienced slightly.
3 - Experienced moderately.
4 - Experienced strongly.

It was explained that the highest rating ("4" or "strong") was for extreme experiences. For an item to be scored as "4", the experience had to equal or excel an experience which the participant considered *strong*, either in comparison to his personal past experiences or to what he would regard as strong in terms of each particular item. The written description and post-drug questionnaire were used as the basis for the ensuing interview. Unclear points were discussed. A tape-recording was made of each interview. A summary of each person's experience and reactions to Good Friday was written by the experimenter.

Six months after the experiment another two-hour period was devoted to each subject. A follow-up questionnaire which consisted of three parts was first completed.[8] Part I was open-ended. The participant was asked to list any changes which he felt were a result of his Good Friday experience, and to rate the degree of benefit or harm of each change. Part II (52 items) was a condensed and somewhat more explicit repetition of items from the post-session questionnaire. Part III (93 items) was designed to measure specific changes in attitude and behavior, both positive and negative. The same rating scale as in the post-session questionnaire was employed in all three parts except that the scale used was from 0-5. A distinction could be made in the highest rating as to whether this experience merely equalled what had previously been thought to be a strong experience ("4"), or excelled it ("5"). Thus "4" and "5" are more precise ratings of what would have been scored as "4" on the 0-4 scale of the post-session questionnaire. In the one-and-one-half-hour interview which followed, most emphasis was placed on a discussion of the nature of any changes which had been indicated. With the aid of Part II, the phenomena of the main categories of the typology were quickly reviewed. The interviewer took a more active role in this part than in the post-session interview. Categories were described in phenomenological terms, and the subject was asked to compare this Good Friday experience to these categories. The response to Part III was used as a basis for fuller description during the interview of any changes in attitude or behavior which had persisted for the six months since Good Friday.
Subjects were also invited to express their feelings about the whole experiment and asked how they would have preferred the set and setting to have been structured. The whole interview was taped. After each interview the experimenter wrote a summary of each subject's experience compared to the mystical typology. Subjects were not told whether they were experimentals or controls. The interviewer himself did not know until after completion of the content analysis of the individual writeups.

The accounts written within a few days after the Good Friday experience and those written six months later (Part I of the follow-up questionnaires) were content analyzed for phenomenological evidence of the categories from the typology of mysticism. The content analysis proceeded in three steps. First, the categories of this typology were described by the experimenter in the form of a training manual for judges who were unsophisticated in both mysticism and psychological experimentation. The description attempted neither to use theological concepts nor to identify the experience as "religious"; it sought instead to describe the phenomenology of the categories of mysticism without naming them as such. These phenomena were described in levels of completeness or intensity, corresponding to the following 0-3 scale for each category:

0 - None, or not experienced at all.
3 - Experienced to a strong degree.
2 - Experienced to a moderate degree.
1 - Experienced to a slight degree.
0 - None or not experienced at all.

The judges were instructed to read the accounts and make a qualitative rating for the highest level attained in each experience for each category or sub-category.[9]

---

[8] See appendix D for a sample of this questionnaire.
[9] See appendix E for the training manual and judges' score sheet.

Second, the category description and rating system were pre-tested on five judges. Originally the plan was to score the content both for qualitative intensity or completeness, and for quantitative number of mentions of each level for each category. The results of this pre-test showed that the category descriptions were in general satisfactory but that there were to many confusing sub-categories. Also, the overlapping nature of the categories made quantitative scoring quite confusing, because the categories were imposed *a priori* on the accounts, rather than derived from the accounts. New, non-overlapping categories were not devised because a major purpose of the content analysis was to determine whether or not phenomena which would correspond to the *a priori* categories were present before the administration of the questionnaire, which could have suggested such phenomena.

Third, the scoring of the categories was revised to a more simple method, and an additional three final judges were trained. These judges were former school teachers who were now housewives and mothers. They did not know the nature or design of the experiment, or that drugs had been given. They were not told that there were experimental and control groups. They were asked to score twenty experiences reported by persons who had attended a Good Friday worship service. The categories were explained by the written description in the training manual, and sample accounts were scored and discussed. All three judges attended the same training session and so were exposed to the same supplemental oral explanation. They received mimeographed copies of the accounts (60 single-spaced typewritten pages) which had been edited to remove all mention of receiving a drug and which were coded to remove all names. A different code was used for the authors of each account and for mention of these same persons in other accounts so that one writer's impression of someone else's experience would not bias the judges.

The accounts were arranged in the same order for each judge. Matched pairs of subjects were placed consecutively with the order of experimental followed by control, or vice versa, determined by a coin-flip. The judges were instructed to read all the accounts through at one sitting and then to proceed with the individual scoring of each account one by one. With enough time allowed to finish all the categories in any account which was started, each judge gave qualitative score to each subcategory or category on a 0-3 scale, as described in the training manual. (Twenty-two items for each account, or 440 in all, were used.) The attempt to score each qualitative level of each item quantitatively was dropped. The scoring procedure was designed so that each account was read five times and different categories scored each time. The easiest categories (e.g., loss of time and space, and positive mood) were scored first. The more difficult categories were then scored after the account became more familiar through repeated readings. This technique was meant to reduce the chance that data would be missed. Each judge estimated that between 15 and 20 hours were required for the scoring of all 20 accounts. The Kendall Rank Correlation Coefficient (γ)[10] was found by comparing ranks of the total scores given be each judge for the same subjects. The ranking procedure using the 0-3 scale was found to be quite reliable. The rankings of the judges' scores were found to have a high correlation with each other ($\gamma = .80$; p less than .001) (See appendix E).

There was *total* initial agreement among all three judges in 68.7% of the 440 items. After each judge's score on each item had been recorded, the three judges held a meeting in which consensus was reached on the remaining 31.3% or 138 items on which there had not been initial total agreement. The experimenter organized the meeting and explained the procedure, but did not participate in the discussion. He only listened to the deliberations from another room to gain an impression of how well the judges had understood the category definitions. For most of the items discussed two of the three judges were already in agreement. Most of the disagreement had been due to one judge having missed a piece of datum rather than a basic misunderstanding of the categories. The ease with which they came to final consensus reflected the good level of initial agreement as well as an adequate understanding of the categories. These final scores were used in statistical calculations which compared the scores of experimental and control subjects.

Chapter V
DATA USED IN MATCHING OF SUBJECTS

Pre-drug Questionnaire and Interview Data

Rating Scale

For use in matching pairs of subjects groups of items from the pre-drug questionnaire were combined into categories which were scored by the experimenter with the following rating scale:

0 - None, or not experienced at all
5 - Very Strong
4 - Strong
3 - Moderate
2 - Slight
1 - So slight as to be Doubtful
0 - None or Not at All

This scale was adapted to the phenomena of each category. These categories and the score distribution for the twenty subjects are listed in table 1.

TABLE 1
DATA USED IN MATCHING PAIRS OF SUBJECTS FROM PRE-DRUG QUESTIONNAIRES AND INTERVIEWS

	Frequency Distribution of Scores					
I. Religious Background	5's	4's	3's	2's	1's	0's
A. Formal religious commitment & practice of parents	1	9	7	1	1	1
B. Religious atmosphere, influence, & training in the home	4	4	7	2	2	1
C. Participation in the life of the church up to high school graduation	4	8	5	1	1	1
D. Theological conservatism	0	2	7	7	4	0
II. Past Religious Experience						
A. Meaningfulness of public worship	0	11	7	1	1	0
B. Conversion or vocational decision experience	7	3	4	6	0	0
C. Certainty of vocational commitment	6	6	7	1	0	0
D. Intensity and regularity of prayer	5	5	5	3	2	0
E. Sense of sin	3	7	4	4	2	0
F. Experiences in nature	0	2	8	6	3	1
G. Transcendence of time and space	0	2	2	2	2	12
H. Sense of presence, mystical union, or experience of the Numinous	0	5	2	5	6	2
I. Joy, blessedness, peace	0	2	4	6	8	0
III. General Psychological Makeup						
A. Moralism	0	0	3	4	4	9
B. Apprehension about participation in the experiment	1	2	6	9	2	0
C. Suggestibility	6	4	4	5	1	0
D. Proverb interpretation	6 Negatives			14 Positives		

Categories

The firs main division of categories was *religious background*. The formal religious commitment and activities of the parents were scored "5" if they were in full-time Christian service such as ministers of missionaries, "4" if they were very active in the life of the church as well as in attendance, "3" if they were faithful in attendance at services but did not participate in many other activities, "2" if they were interested enough to be irregular attenders, and "1" if they were only interested enough to send their children to Sunday school or church. Religious atmosphere, influence, and training in the home were scored "5" if there were regular and meaningful family worship, prayers, grace, and religious discussions; "4" if only some of these activities were regularly practiced but in a meaningful way; "3" if they were irregular and partial, but meaningful; "2" if they were irregular, partial, and generally unmeaningful; and "1" if they were only occasional. Participation in the life of the church through high school graduation was scored "5" if the person regularly, actively, and meaningfully participated in all the activities of the church which were available to him such as Sunday school, church, young people's meetings, and summer church camp, "4" if he participated regularly and meaningfully as an attender but took no active part in planning or helping, "3" if he participated only in some of the activities he could have, "2" if he was an irregular participator because he found such activities not particularly interesting or meaningful, "1" if only an occasional participator; and "0" if he did not participate at all. The preparation for, and meaningfulness of, joining the church were also given consideration in this score. Theological conservativism was scored according to degree of orthodoxy, with "5" representing fundamentalism; "3" neo-orthodoxy, and "1" the most liberal liberalism. "4" and "2" indicated gradations between these positions. Theological discussions, however, were avoided during the interview.

The second major division of categories and the one on which the most time was spent during the pre-drug interview was *past religious experience*. Meaningfulness of public worship (including communion services) was scored "5" if it was usually very meaningful; "4" if it was sometimes very meaningful; "3" if it was usually moderately meaningful; "2" if it was usually slightly meaningful; and "1" if it was usually unmeaningful. Conversion or vocation decision experience was scored according to the intensity of original emotional expression in relation to the present significance of the experience. A "5" experience was one that was sudden, climactic, dramatic, and intense and provided considerable emotional release. The person at the time of the interview still regarded the experience as a peak experience, a turning point, and still significant in his on-going life. A "4" experience was similar but not as intense, although still meaningful. A "3" experience was similar to "5" or "4" in intensity of original emotional expression but one which was not still considered particularly important, valuable, or meaningful. A "2" experience did not have the sudden or "twice-born" character, but was a slowly-dawning gradual decision which was made after considerable thought, yet remained very significant for the on-going life of the subject. A "1" experience was purely a gradual intellectual decision without much emotional involvement.

Certainty of vocational commitment combined such elements as sense of call, dedication, and definiteness of future plans, but was scored on strength of certainty. Intensity and regularity of prayer life (exclusive of public worship) were scored "5" if the person had an active and regular personal devotional life which had great meaning for him. Sin combined both general and specific senses of sin.

The more characteristic mystical elements were divided into four categories: 1) experiences in nature; 2) transcendence of time and space; 3) sense of presence, mystical union, or experience of the Numinous; and 4) joy, blessedness, and peace. These categories were scored "5" only if they corresponded to the most complete or intense degree of the typology of mysticism. A score of "4" meant a definite though less complete resemblance. Lesser degrees were scored from 1-3 with a score of "1" having only the faintest general similarity.

The third main division was *general psychological make-up*. Moralism was evaluated by asking the person about his attitude toward smoking and drinking in himself and others. A score of "5" indicated a very puritanical and legalistic attitude. The degree of apprehension that the person felt about participation was scored after review of several points in the interview. There had been a discussion of direct fears about immediate or long-term effects, the appropriateness of using drugs in a religious service (to discover any prejudice against such an experiment), and the motivation for volunteering. The person had also been asked how apprehensive he felt. A score of "5" for suggestibility meant that the person fell backwards almost immediately without trying to fight the suggestion of the wind. Scores of 4-2 represented persons who eventually fell with varying degrees of resistance. A score of "1" meant that the person did not fall backwards, but was suggestible enough so that he had to fight to maintain balance. Each person's interpretation of the proverb about the rolling stone was listed as either P (for positive), meaning that a person who keeps active and moving does not get stagnant, or N (for negative), meaning that a person who doesn't settle down to one thing is shiftless and will never accomplish anything. This was assumed to be one measure of the person's background and general outlook on life.

The data in table 1 show the homogeneity of the volunteers in terms of religious background, interest, and experience. Other pre-drug questionnaire data also supported this conclusion. The very fact that they were all undergoing professional training for the Christian ministry at a denominational seminary tended to serve as a screening factor. All volunteers were healthy young males between the ages of 22 and 35. The average age was 24. 17 out of the 20 were first year students and had recently graduated from college. They were all from the free church tradition. Denominations represented were Baptist (9), United Church of Christ (7), Congregationalist (1), and Swedenborgian (3).

Description of Average Subject

The average subject came from a home where there was interest in religion but not in an extreme way, and the parents were active in the church. He attended Sunday school as a child and joined the church in his early teens. During high school he attended the church youth group and perhaps went to summer church camp. The decision to take ministerial training was a gradual one which was made during college after much consideration of vocational possibilities. It was done with serious commitment although at present the exact type of ministry was not certain. At some point there had been a sudden conversion which was prompted by the kind of religious service which stressed a "personal decision for Christ" in order to be "saved". The theology behind the experience had been rethought and modified, but the experience was regarded as important in the religious development of the person. His theological position was neo-orthodox. He was generally unfamiliar with the characteristics of mystical experience either through experience or reading. The elements which were present were only of low intensity and completeness. Prayer was regarded as important and some kind of private devotional life was practiced in addition to public worship, which was usually moderately meaningful. Sense of sin was moderately well developed. Moralism was low. There was openness to the possibility of a meaningful religious experience through the use of psilocybin. Apprehension about participation was moderate. Suggestibility was high.

California Psychological Inventory Data

Certain categories of the California Psychological Inventory were chosen as most relevant for matching subjects whom it was hoped would have similar natural inclination for the mystical state of consciousness. The assumption was made that psychological make-up would have something to do with the potentiality for such experiences. The categories which were used in matching are listed in table 2 which gives a summary of the range of scores, median score, and average score for each category. As a whole the medians and averages were all between 55 and 63 except for socialization and self control which were just below 50. There were more scores above 50 than below and not too many extremely high or low scores. The majority of scores were between 40 and 60. Self acceptance had the most scores above 60. Flexibility had the widest range (37-79).

TABLE 2
FROM THE CALIFORNIA PSYCHOLOGICAL INVENTORY: RELEVANT SCORES USED IN MATCHING PAIRS OF SUBJECTS

Categories	Range of Scores	Median Scores	Average Scores
Sa (self-acceptance)	41-82	63.0	63.7
Wb (sense of well-being)	26-66	56.0	53.15
So (socialization)	29-61	48.5	49.85
Sc (self-control)	34-62	47.0	48.2
To (tolerance)	32-69	59.0	58.5
Py (psychological-mindedness)	47-69	59.5	59.9
Fx (flexibility)	37-79	62.5	62.5
Fe (femininity)	34-70	55.0	53.0
Sy (sociability)	39-65	59.0	57.8

The data in tables 1 and 2 plus the general impression from the two-hour interview were used in matching the twenty subjects into ten pairs. The categories listed under past religious experience were given the most weight, especially the more mystical elements, conversion or vocation decision experience, vocational commitment and devotional life. Next in importance were the categories under religious background. Categories under general psychological make-up and scores on the California Psychological Inventory were not given as much weight in the matching decisions. The general impression of the person by the interviewer also played a significant part, especially where the other data did not indicate a clear cut match. The pairings were done mostly on the basis of subjective impressions by the interviewer, because he scored the pre-drug questionnaires, but were done before the administration of the drug. The initial impressions which the volunteers gave were confirmed, rather than changed, by subsequent interviews.

Chapter VI
DATA FROM QUESTIONNAIRES, INTERVIEWS, AND CONTENT ANALYSES

Data Relevant to the Categories of the Typology of Mysticism

Method of Presentation

The available data for each category will be discussed separately, and the relevant information from the methods used to measure each category will be compared. The post-drug questionnaire (within one week), followup questionnaire (six months later), and judges' content-analysis of individual accounts (written a day or two after the experience as well as after six months) complement each other and measure the same category from different perspectives. For example, the followup questionnaire was not an attempt to repeat the same individual items exactly as in the post-drug questionnaire, but to measure the same category in a clearer or more precise way. The judges' score was on most cases a single category score which was based on the definition of each category as explained in the training manual. Each category will also be illustrated by quotations from individual accounts and tape recordings.

The single-tailed, non-parametric Sign Test was used throughout in statistical calculations of significance levels both for individual items and items combined into categories.[1] For each pair the score or sums of scores (for more than one item) of the control subject was subtracted from the comparable score of the matched experimental subject, and the number of differences was counted. In the tables "N" is the number of pairs with a difference (differences of 0 were not counted); the statistical calculation took into account the relative number of differences with a positive or negative sign. The prediction was made for most of the phenomena measured that the experimental subjects who took psilocybin would score significantly higher than the controls. The items for which a higher control score was predicted will be indicated.

The items used for each method of measurement were listed for each category with the level of probability (*p*) that the difference between the experimentals and controls was due to chance. A *p*-value less than .05 means that the experimentals (as predicted unless otherwise indicated) scored significantly higher than the controls on the phenomena described by that item or category. In other words there would be less than five chances in one hundred that the observed difference was due to chance rather that to psilocybin. The *p*-values were listed for individual items which measured the category for groups of items within the category, and for each category as a whole (i.e., the combination of all the items in the category).

The scores of the combined items in each category or sub-category were summarized in table form.[2] The frequency distribution of scores at comparable levels on the rating scale of each method of measurement were listed (i.e., the number of *times* that the ten experimentals or controls responded at each level). The total numerical sum of all scores at all levels for the ten experimentals and ten controls was listed next to the maximum possible score (i.e., the numerical sum obtained if all subjects had scored all items at the highest possible level). The *p*-value for the combination of items was also indicated.

The data were arranged to answer four questions for each category. Each question expressed a progressively more rigorous examination of the data to elicit the similarities and differences between the phenomenology of the drug experience and that of the mystical typology. 1) Did the experimentals score significantly higher that the controls on a combination of the scores of all items in the category? This question was answered by the *p*-value for the category. 2) If there was a significant difference in the category as a whole, was it because of high or low scores? The difference between "4" and "0" and "1" and "0" counts the same under the Sign Test. This question was answered by a comparison of the total score and frequency distribution for experimentals

---

1. For a detailed explanation of the Sign Test and the tables used see Siegel, *op. cit.*, pp. 65-78.
2. See appendix F for a more detailed explanation of the columns and symbols used in the tables.

and controls. 3) Which individual items in the category showed a significant difference between experimental and control scores? This question was answered by each item's *p*-value, which was calculated using all scores on the scale for that item. 4) Did the difference in these items remain significant if only the scores at the top of each scale were used in calculation of the difference? This question was answered by another application of the Sign Test to the items selected in question 3, but all differences which were obtained from scores of "moderate" or lower were counted as 0. This loss of data would be expected to increase the probability (p) that the difference between experimentals and controls was due to chance unless, in fact, the difference was originally due a strong scores, which would indicate that this phenomenon of the mystical typology had been experienced to a complete degree. The cluster of items which emerged as most significant were then compared to the original definition of the category.

Another technique of analysis was also employed. In some categories the number of items which contributed to the category covered a broad range. Some of these items corresponded more closely to the *a priori* definition of the category than others which were more supplementary but which helped to gather all evidence for the category. Therefore, not only will the results of the combined scores of all items related to the category be given, but also the combination of only those items most crucial to the category as defined in the mystical typology above. The use of this technique added precision to the analysis. The significance level of these essential items when only "strong" scores were used was a valuable measure of the completeness of the category.

Category I: Unity

As shown in Table 3, the experimental subjects scored significantly higher than the control subjects on the category of unity as w whole when the scores of individual items in all subcategories were combined (*p* less than .002 for all three methods of measurement). In other words there were only two chances in 1000 that this difference was due to chance rather than to psilocybin. The score distribution revealed that the experimentals had higher total scores and many more "strong" scores (maximum possible on various rating scales) than the controls, who had relatively few scores as high as "moderate" and a predominance of scores of "0".

Each subcategory was analyzed both as a combination of items and item by item in order to discover the contributing factors to the significance of the data as a whole.

TABLE 3
Category I: UNITY
Combination of All Subcategories

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics

2 Content Analysis:	Exper:	9	5	2	14	39	60	9	.002
	Contr:	0	1	0	29	2	60		

Internal Unity

As shown in Table 4 the subcategory of internal unity as a whole was significant at the .002 level for all three methods of measurement. The score distribution revealed that with all three methods the experimentals had had more total score and a predominance of scores at the top of the scales, while the controls had only a few scores as high as moderate and a predominance of scores of "0".

TABLE 4
Category I: UNITY
Internal Unity

	Contr:	0	5	1	34	17	160		
6 Follow-up: F18, F19, F33, F42, F43, F47	Exper:	33	2	8	18	178	300	9	.002
	Contr:	0	4	3	53	16	300		
1 Content Analysis: C7	Exper:	6	3	0	1	24	30	9	.002
	Contr:	0	1	0	9	2	30		

The eleven individual items which measured this subcategory are listed in Table 5 with the probability of each that the higher scores of the experimentals were due to chance rather than psilocybin. All the individual items had a *p* less than .008 except F43 which is the same as F42 only with a negative rather than positive value judgment by the subject about the phenomenon of loss of self. The fact that F43 did not show a significant difference between experimentals and controls would imply that the experimentals regarded their experience of loss of self as more positive than negative. When highest possible or "strong" scores were used in computing differences between pairs of experimentals and controls, only P74 (unity with ultimate reality) lost its significance (*p* less than .063). Perhaps this loss was due to the addition of the interpretive phrase, "ultimate reality," as was suggested by several subjects during the interviews. The items which were most essential to the definition of internal unity (loss of sense of self, loss of all sense impressions, and pure awareness) remained significant at the .04 level and most of the items were significant at the .01 level. All three methods of measurement were consistent.

The content analysis data illustrated these essential elements:

TABLE 5
LIST OF ITEMS USED TO MEASURE *INTERNAL UNITY*

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug questionnaire data (4 items):		
P9 Loss of self:	.001	.008
P72a Sense of the loss of the multiplicity of all particular sense impressions:	.004	.016
P73 Pure awareness with no empirical distinctions (i.e., one is beyond the self-consciousness of sense impressions, yet one is not unconscious):	.002	.008
P74 Sense of unity with ultimate reality at the level described by 72a & 73:	.008	(.063)
(2) Follow-up data (6 items):		
F18 Loss of your own identity:	.004	.008
F19 Pure awareness beyond any empirical content:	.002	.004
F33 Fusion of the self into a larger undifferentiated whole:	.008	.032
F42 Loss of sense of self as a predominantly positive experience:	.004	.008
F43 Loss of sense of self as a predominantly negative experience:	(.13)	(.25)
F47 Freedom for the limitations of the self in connection with a unity or bond with what was felt to be all-encompassing and greater-than-self:	.004	.032
(3) Content-analysis data (1 item):		
C7 Internal unity:	.002	.016

Experimental Subject RM:

> I saw the cosmos. It was all molten plastic. Then I knew that I must be somewhere there. Where was my self? What am I? Where am I in the real (plastic) world? Then I was afraid no more. My self is no one place, but in many places. It floats, I float. Body is not real. Only the adventurous *self* is real. The adventurous self floats into all Being, the orange plastic cosmos. It leaves the old ego behind. The old ego is behind but it glows like a far away harbor light. I can always return.

(Comment: This is a good example of lostness of self and unity with all Being, symbolized by "the orange plastic cosmos").

Experimental Subject KR:

> I found myself grunting in agreement or mumbling "Of course, it has always been this way" over and over again as the panorama of my life seemed to be swept up by this unifying and eternal principle. ... I seemed to relinquish my life in "layers"; the more I let go, the greater sense of oneness I received. As I approached what I firmly believed to be the point of death, I experienced an ever greater sense of an eternal dimension to life. There seemed to be infinite possibilities of time and space.

Experimental Subject QX:

> I lapsed into a period of complete lostness of self that must have lasted for an hour but seemed very brief. This was a blank sensation, better still, a void. ... My experience seemed to be dominated by a sense of *oneness*, *unity*, and *harmony*.

(Comment: This resembles the classical phenomenological description of undifferentiated unity with pure awareness yet no specific content and loss of usual sense of self.)

The evidence from total scores of all items, frequency distribution, and individual item analysis has indicated that psilocybin induced the phenomena of internal unity in the experimental subjects to a rather complete degree.

External Unity

As shown in Table 6, this subcategory was significant at the .016 level for all methods of measurement. The distribution of scores revealed that the controls hardly experienced the phenomena of external unity at all and none to more than a slight degree. The predominance of high scores for the experimentals was not so marked as in the case of internal unity. All individual items were significant at the .032 level except oneness through objects other than people (C8), which had a *p* greater than .25. C8 is more crucial to the definition of external unity than oneness through people (C9), unless the underlying unity of the whole external world were experienced through people as the means for the expression of this deep and broad unity of all things. For his to be the case, however, the highest scores on the judges' rating scale should have been used (i.e., "3's"), but for both C8 and C9, *p* is greater than .25 when only these top scores were used.

TABLE 6
Category I: UNITY
External Unity

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items	**(*n*=10)**	**Strong**	**Moder.**	**Slight**	**None**	**Actual**	**Maximum**	***N***	***p***
4 Post-drug: P68, P69, P70, P71	Exper:	14	4	8	14	80	160	8	.008
	Contr:	0	0	4	36	5	160		
3 Follow-up: F25, F37, F44	Exper:	11	0	5	14	58	150	6	.016
	Contr:	0	0	1	30	2	150		
2 Content Analysis: C8, C9	Exper:	3	2	2	13	15	60	6	.016
	Contr:	0	0	0	20	0	60		

The dissolving of the subject-object dichotomy (P68) and loss of feelings of difference from objects (F25) are essentially the same phenomenon and were the only items which remained significant at the .032 level under such a rigorous treatment of the data. This phenomenon is an important element in the experience of external unity and is alone enough to make the data from this category qualify as an example of this subcategory of the mystical typology. Against this evidence must be placed the lack of confirmation from the judges. The content analysis data showed a greater depth of underlying cosmic unity or oneness through people than through objects.

Experimental Subject HQ:

> Couple of times I kicked against YS's leg accidentally, and I opened my eyes, for my foot seemed to combine with his left leg.

Experimental Subject QX:

> I remained in a bent a prayerful position, but I was not praying. What seemed to be happening was my becoming complete, i.e., my body was whole or one. My arms seemed to merge into my body, yet I knew I still had arms. I could rub my hands into my legs, yet I still had hands. Everything was a part of the other yet distinct in itself. From this, I moved to a oneness with the pews, both the one I was sitting on and the one in front of me. The pew seemed to be giving itself to me when I would turn in my seat or assume different positions. It seemed to "give" to my movements all the while aiding and giving to my comfort. Even my legs which touched against the pew in front of me seemed to find an extremely giving and helping friend in the wooden pew.

(Comment: These two examples of the dissolution of the subject-object dichotomy do not have the cosmic dimension at this point in the experience.)

Experimental Subject KR:

> Early in the sequence, the "I"-"You" structure broke down both in relation to my inner experience and to the others in the room. A sense of "we-ness" took its place eventually.

Experimental Subject QX:

> My attention was directed toward L6 when I felt a sensational oneness with him. I felt he and I had seen and interpreted life as it truly was meant to be understood, i.e., as man in harmony and love and oneness through all eternity.

For more examples of oneness through people see the section on love in Category III below.

TABLE 7
LIST OF ITEMS USED TO MEASURE *EXTERNAL UNITY*

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug questionnaire data (4 items):		
P68 Paradoxical dissolving of the subject-object dichotomy in spite of the empirical multiplicity of objects (they are still perceived as separate):	.008	.016
P69 Intuitive experience of the essences of objects:	.016	(.13)
P70 Sense of unity with these objects:	.008	(.13)
P71 Felt awareness of the life or living presence in all things:	.032	(.25)
(2) Follow-up Questionnaire data (3 items):		
F25 Loss of feelings of difference from objects:	.016	.032
F37 Intuitive experience of the essences of objects:	.032	(.63)
F44 Sense of unity with objects:	.032	(.5)
(3) Content-analysis data (2 items):		
C8 Oneness through external objects other than people:	(.25)	(1)
C9 Oneness through people:	.032	(.25)

The strongest evidence for external unity is from the questionnaire data because of the dissolution of the subject-object dichotomy. The content analysis failed to show the depth and breadth necessary for the most complete level. We conclude, therefore, that the phenomenon of external unity did occur in the experimental subjects but in an incomplete way.

Supplementary Phenomena

The items in this subcategory as explained in the typology are corroborative, but not definitive, phenomena which occur in connection with either internal or external unity or both. Table 9 lists these items and their significance levels which indicate that the experimentals showed significantly higher scores than the controls (*p* less than .016) for most individual items. Only P77 (consciousness of a "Beyond" or "More") and P67 (sense of being a part of a larger whole) showed no significant difference between experimentals and controls. During the interviews several subjects commented that the "Beyond" or "More" seemed to imply a theological interpretation which they were not ready to make. Only items F36 (feeling of completeness) and F49 (unity with ultimate reality) lost significance when only "strong" scores were used. In F49 the interpretive phrase "ultimate reality" (cf. P74) may have been responsible.

As seen in Table 8 the scores of the experimentals compared to those of the controls followed the same pattern in score distribution and significance level of difference, as for the category of unity as a whole (*p* less than .001). We conclude that these closely related items strengthen, and certainly do not weaken, the conclusions made about the subcategories "internal" and "external unity."

P77 Consciousness of a "Beyond" or "More":	(.15)	(.15)
P78 Expansion of usual personal consciousness to other dimensions *within* the self:	.001	.008
P79 Expansion of usual personal consciousness to other dimensions *beyond* the self:	.004	.004
P96a Sense of belonging to a new and greater unity during the experience:	.008	.063
(2) Follow-up questionnaire data:		
F31 Expansion of usual personal consciousness to other dimensions *within* the self:	.001	.001
F32 Expansion of usual personal consciousness *beyond* the self:	.004	.016
F36 Feeling of completeness:	.004	(.13)
F41 Sense of belonging to a new and greater unity:	.008	.016
F49 Unity with ultimate reality:	.016	(.13)

Category II: Transcendence of Time and Space

As is shown in Table 10, this category as a whole had significantly higher scores for experimentals than for controls (*p* less than .001 for all three methods of measurement). The distribution of scores showed a predominance of high scores for the experimentals and "0's" for the controls. On the basis of total scores, controls experienced these phenomena to a negligible extent. As shown in Table 11, when the subcategories of time and space were analyzed separately, all the differences between experimentals and controls were in the same direction as in the analysis of the category as a whole (*p* less than .001 for time and less than .004 for space). In other words there were less than four chances in 1000 that this transcendence of time and space was due to chance rather than psilocybin.

The individual items which were used to measure the subcategories of time and space are shown in Table 12. All individual items were significant in the same direction (*p* no greater than .004 for any item). When only the "strong" level scores were used, all the items remained significant on at least the .016 level.

Examples of the loss of sense of time were numerous in the content-analysis data:

(1) Transcendence of Time		
a. Post-drug questionnaire data:		
P75 Transcendence of time in the sense defined by items 72a to 74 (internal unity):	.002	.004
P80 Transcendence of time in the sense defined by items 77 to 79 (supplementary phenomena of unity):	.001	.002
b. Follow-up questionnaire data:		
F1 Loss of usual time sense:	.001	.001
F26 Eternity:	.002	.008
F35 Timelessness:	.004	.008
c. Content-analysis data:		
C1 Loss of usual sense of time:	.001	.004
(2) Transcendence of Space		
a. Post-drug questionnaire data:		
P72 Paradoxical transcendence of space as defined in items 68 to 71 (external unity):	.004	.008
P76 Transcendence of space in the sense defined by items 72a to 74 (internal unity):	.004	.008
P81 Transcendence of space in the sense defined by items 77 to 79 (phenomenon of unity):	.004	.004
b. Follow-up questionnaire data:		
F2 Loss of usual awareness of where you were:	.002	.016
F34 Spacelessness:	.004	.016
c. Content-analysis data:		
C2 Loss of usual sense of space:	.001	.004

Experimental Subject HQ:

> It seemed that I was there for the longest time. I recall looking at the clock again and again, but it didn't change.

Experimental Subject SE:

> I kept looking at my watch and thinking, looking and thinking, looking and thinking - time seemed to stand still, to be endless.

Experimental Subject QX:

> Matter and time seemed to be of no consequence. I was living in the most beautiful reality I had ever known, and it was eternal.

Experimental Subject CZ:

> Space and position were meaninglessness - I could as well have been wandering lost on the moon.

Experimental Subject GP:

> The place was nowhere I had ever been, nor any place that I belonged in. I was afraid sometimes that there was nothing outside, or before, or after ... I did not know where I was, nor when it was, nor where I had come from nor how long I had been there.

Experimental Subject EB:

> Somewhere about this time I lost contact with myself ... There was no center; there was no sense of time; there was no sense of space in the physical sense. I just felt a sense of unity with an endless world of abstract, colorful beauty which didn't seem to be going anywhere, but just was...

(Comment: Some of these examples show that transcendence of time and space is an integral part of the experience of internal unity.)

We conclude from the data presented in this section that the transcendence of time and space, corresponding to the most complete degree defined by our typology of mysticism, was experienced by the experimental subjects who took psilocybin.

Category III: Deeply Felt Positive Mood

As shown in Table 13, the experimental subjects scored significantly higher than the controls when the scores of individual items in both subcategories of deeply felt positive mood were combined (*p* less than .020 for all three methods of measurement). The frequency distribution of scores revealed that all of the highest scores were recorded by the experimental subjects, and the controls recorded the great majority of the "0's". In the middle range of the rating scales, however, the balance was more even between experimentals and controls.

For more precise analysis, the two subcategories were treated separately.

	Contr:	0	0	3	27	3	90		

The most universal phenomena (Joy, Blessedness, and Peace)

As seen in Table 14, the combined scores of the sixteen items describing joy, blessedness, and peace were significantly higher for experimentals than controls from all three methods of measurement (*p* less than .020). Although the controls scored these phenomena on the lower ranges of the scoring scales, the highest scores were exclusively from the experimentals as seen from the total scores and frequency distribution. These items are listed in Table 15. All items which were aspects of joy were significant at the .020 level except F13, happiness. *No* individual items under blessedness and peace were significant (*p* greater than .063 in all cases). When only the "strong" scores were used, exultation (P39), ecstasy (F13), delight (F29), and joy (F39) remained significant (*p* less than .032), but important items which lost their significant difference were ecstatic joy (P52) and joy (C3) (*p* less than .063).

TABLE 15
LIST OF ITEMS USED TO MEASURE THE MOST UNIVERSAL PHENOMENA OF DEEPLY FELT POSITIVE MOOD (JOY, BLESSEDNESS, AND PEACE)

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug data (7 items):		
P39 Exultation:	.020	.032
P44 Exuberance:	.002	(.13)
P50 Overflowing energy:	.008	(1)
P52 Ecstatic joy:	.004	(.063)
P14 Sense of well-being:	(.38)	(.38)
P47 Blessedness:	(.15)	(.15)
P49 Peace:	(.09)	(.09)
(2) Follow-up questionnaire data (7 items):		
F11 Ecstasy:	.004	.016
F13 Happiness:	(.23)	(.23)
F29 Delight:	.016	.016
F39 Joy:	.016	.032
F46 Exultation:	(.37)	(.37)
F12 Peace:	(.50)	(.50)
F45 Blessedness:	(.11)	(.13)
(3) Content-analysis data (2 items):		
C3 Joy:	.020	(.063)
C5 Peace or blessedness:	(.063)	(.13)

Experimental Subject KR:

> Having died only to have life given back gave me a tremendous sense of exultation and manliness. I grasped the back of the pew or wooden upright in front of me as I exclaimed and I delighted in the heightened sensations of all five senses.

Experimental Subject GP:

> I heard PK (or whoever it was) return to the chapel and play "Jesus Christ is Risen today, Hallelujah!" I had a brief but violently intense feeling of joy.

Experimental Subject FK:

> Then I read the Scripture, put out the candles (which I believe to be symbolic of the crucifixion of Christ), and after more *blackness*, found myself in the pulpit, preaching about love and peace. ... I attempted to play the organ, wanting to play "Christ the Lord is Risen Today," being motivated by a strange sense of joy in the reality of this event.

(Comment: This example shows the close relationship between various elements of positive mood as well as their possible close interrelation with sense of sacredness.)

Other evidence of blessedness and peace combined with a sense of sacredness is as follows:

Experimental Subject KR:

> Opening my eyes I noticed that tears were streaming down L1's face, that we were all caught up in a glow of holy light from off the altar, that we were all participating in one great cosmic drama of all races, creatures and eras, in short, that we were experiencing beatitude.

Experimental Subject QX:

> There seemed to be complete support from all the surrounding elements; no hostility at all was present in anything. I would on occasion lower my head and close my eyes as if to pray and would seem to be in the realm of eternity. It was sheer bliss and something I didn't want to leave.

Control Subject BL:

> Such communion with God as I experienced on Good Friday is not quite the same as another experience with the Divine which I describe through such terminology as "being grasped," or melting." I did not approach this experience of "exalted or divine tenderness" which in the past has caused me to feel one with everything that is. The peace which comes through this experience was missing from the worship Service on Good Friday.

This control subject did not experience the most profound peace he has ever known but he did score peace and blessedness at a level of "moderate" degree. Other controls also scored these items. The experimentals in general did not score peace to the most complete degree as shown by the lack of significant difference between experimentals and controls on each individual item which measured these phenomena.

We conclude that although the subcategory as a whole showed a significant difference between experimentals and controls, the difference was due to the usually intense joy which was a part of the psilocybin experience. Because all the data were not consistent in measuring this joy at the highest intensity, we conclude that the experience of the experimentals was not the most complete example of the joy described by your typology for this category.

Closely Related Phenomena (Love)

Although love is not one of the *universal* characteristics of the typology of mysticism, the experience of love may occur in connection with joy, blessedness, and peace. As seen in Table 14, the experimentals experienced the phenomena of love more than the controls at a significance level of .055 in the follow-up data and .035 in the content analysis data. The experimentals had higher total score and had more strong scores with each method of measurement. The reason for no significant difference in the post-drug data was that the controls also scored this phenomenon (total score of 126 for experimentals and 107 for controls).

The nine items which were used to measure the phenomenon of love are listed in Table 16. Individual items were mostly not significant at the .05 level except for P41, F24, and C4 (*p* less than .035). The only item which remained significant when only "strong" scores were counted was F24, deep interpersonal relations (*p* less than .035).

Cosmic love such as love of God was not significant. Psilocybin seemed to increase depth of interpersonal relationships on a very human level both for experimentals and the controls with whom they interacted.

TABLE 16
LIST OF ITEMS USED TO MEASURE LOVE

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug questionnaire data (5 items):		
P41 Love:	.035	(.063)
P43 Tenderness:	(.66)	(.66)
P90a Feeling of love toward others:	(.38)	(.38)
P122 Did you particularly like or feel close to either of leaders?:	(.11)	(.25)
P124 Did you particularly like or feel close to any participant in the experiment?:	(.35)	(.35)
(2) Follow-up questionnaire data (3 items):		
F24 Deep interpersonal relations with other people present:	.035	.035
F28 Love:	(.26)	(.26)
F51 Love of God or Christ:	(.26)	(.26)
(3) Content-analysis data (1 item):		
C4 Love:	.035	(.25)

Some examples of such love from the content-analysis data are as follows:

Experimental Subject EB:

> There was a certain feeling that all people were good, and that I wanted to *love* them for it.

Experimental Subject FK:

> However, my strongest feelings were toward L3, who in a sense wanted to help me. Never before have I sensed such a feeling of *filia* (Greek for love, i.e., friendship); he represented the forces of good, forcing me to face my frailty and human fallibility; ... I felt that the only one who really understood me when I was "under", was L3, for he understood what I was going through, for he had undergone the same experience himself. This alone, not counting the other far more significant aspects of my experience, would make the situation of real value.

Experimental Subject QX:

> I looked up at the front of the Chapel but the light seemed to be too bright for my eyes and I had to lower my head. I was overcome by a feeling of oneness with L6 and FK. I seemed to be caught up in a realm of complete understanding of them and with them.
> All this time, I felt a strong pull to FX - which said to me he needed my support if nothing else. I saw him as himself but also as representing all men, and I knew deep within that I could not turn my back of him. At that time, I went over and sat by him. I did not speak a word. I just sat in a chair between him and L6. Another fellow was sitting on the sofa with FK, and during one of the songs he and FK clasped hands and this was very beautiful and significant to me, for I saw two men at one with each other in genuine love existing in eternity.

(Comment: The depth of oneness expressed by QX is an example of the oneness through people which can be part of the subcategory "external unity." This example shows the relationship between the two subcategories of "love" and "external unity.")

Control Subject NJ:

> FK went to the altar, turned around, and showed us his face - a face I had never seen before on a human being. This caused the service to be more meaningful than ever before - why? Although FK moved up to the altar with a vigorous drive, clutched the cross firmly, exhibiting such strength, and a first seemed as if he was going to tear everything from one end to the other, he turned and showed himself differently. His face showed as much love, gentleness, sincerity and strength to bear real suffering as any face has ever shown.

(Comment: NJ's experience of love was caused by the experimental subject FK's experience.)

We conclude, therefore, that although the category of "deeply felt positive mood" was significant as a whole for all three methods of measurement, psilocybin produced the most significant difference between experimentals and controls in this category in the experience of joy. There was also a difference in the experience of love on a human level for the most part, but not so significantly, and the experience of blessedness and peace was not significantly different between experimentals and controls.

Category IV: Sense of Sacredness

As seen in Table 17, the combined scores of all items related to this category were significantly higher for the experimentals than for the controls from the post-drug data (*p* less than .020). From the follow-up data, the significance level was .055, and the content-analysis data showed no significant difference (*p* equal to .37). In other words, the evidence is very suggestive but not conclusive that psilocybin induced a sense of sacredness in the experimental subjects. In all methods of measurement, a basic pattern in the data was reflected by the frequency distribution of scores. The top-of-the-scale scores were made almost exclusively by the experimentals. The controls, however, had more total middle-range scores than the experimentals did.

TABLE 17
CATEGORY IV: SENSE OF SACREDNESS
Combination of all Subcategories

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items	**(*n*=10)**	**Strong**	**Moder.**	**Slight**	**None**	**Actual**	**Maximum**	***N***	***p***
13 Post-drug:	Exper:	52	23	22	33	304	520	9	.02
	Contr:	1	25	55	49	173	520		
8 Follow-up:	Exper:	43	5	12	20	231	400	10	.055
	Contr:	3	10	30	37	99	400		
1 Content Analysis:	Exper:	4	1	0	5	14	30	8	(.37)
	Contr:	0	2	4	4	8	30		

The twenty-two items which were used to measure sacredness are listed in Table 18 with the probability that the difference found in each case was due to chance rather than psilocybin.

Only eight out of these twenty-two individual items showed a significant difference between experimentals and controls at the .035 level, and one more item (humility - P61) was close to being significant (*p* equal to .062).

TABLE 18
LIST OF ITEMS USED TO MEASURE SENSE OF SACREDNESS

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Phenomena with implicit indication of sense of sacredness:		
a. Post-drug data (6 items):		
P7 Sense of wonder:	.004	(.13)
P56 Sense of awe or awesomeness:	.011	.016
P58 Mysterious fascination in spite of terror or fear (in the sense of a shaking or trembling in the utmost depths of your inner being):	.008	(.13)
P59 Sense of the wholly-otherness of what was met in the experience:	.035	(.063)
P6 Sense of finitude:	(.23)	(.23)
P13 Sense of humility:	(.35)	(.35)
b. Follow-up data (2 items):		
F22 Awe:	.011	.011
F14 Sense of presence of what can only be described as nameless:	.032	(.063)
(2) Phenomena with explicit mention of holy, sacred, or divine:		
a. Post-drug data (7 items):		
P61 Sense of profound humility before the majesty of what was felt to be sacred or holy:	(.063)	(.063)
P60 Sense of your own finitude in contrast to the infinite:	(.090)	(.090)
P77 Consciousness of a "Beyond" or "More":	(.15)	(.15)
P62 Sense of presence of what was felt to be sacred or holy:	(.64)	(.64)
P57 Sense of reverence:	(.78)	(.78)
P83 Contact or bond with God:	(.64)	(.64)
P82 Sense of the presence of God:	(.83)	(.83)
b. Follow-up data (6 items):		
F48 Sense of being at a spiritual height:	.016	.032
F30 Sense of your own finitude in contrast with the infinite:	.020	.032
F51 Love of God or Christ:	(.26)	(.26)
F15 Sense of sacredness with which you regarded your experience:	(.37)	(.37)
F40 Sense of reverence:	(.50)	(.50)
F50 Sense of the presence of God:	(.50)	(.50)
c. Content-analysis data (1 item):		
C6 Sense of sacredness:	(.37)	(.37)

When only "strong" scores were used, the items which remained significant were: awe (F56 and F22), sense of finitude in contrast with the infinite (F30), and spiritual height (F48) - *p* less than .032 for all four items. Sense of wholly otherness (P59) and sense of nameless presence (F14) were almost significant (*p* less than .063) under this rigorous analysis. The other two items which complete the list of eight significant ones were: wonder (P7) and mysterious fascination in spite of terror or fear (P58).

Six of these eight significant items were phenomena with an implicit indication rather than explicit mention of the holy, sacred, or divine. The items which were most explicit, such as reverence (P57 and F40), sacredness (F15), sense of Presence (P62), consciousness of "Beyond" (P77), or those which mention God (P82, P83, F50, and F51), were *not* significant at the .05 level.

For the purpose of a more precise analysis, the explicit and implicit items in the post-drug and follow-up data were combined separately. As shown in Table 19, the experimentals scored significantly higher than the controls on the implicit group (*p* less than .02 for both methods) but not on the explicit (*p* less than .09 for both questionnaires). In other words there were only two chances in one hundred that this implicit phenomena experienced by the experimentals was not due to psilocybin.

TABLE 19
Category IV: SENSE OF SACREDNESS

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items	**(*n*=10)**	**Strong**	**Moder.**	**Slight**	**None**	**Actual**	**Maximum**	***N***	***p***
Phenomena with implicit indication of sense of sacredness

	Contr:	1	8	22	29	62	240		
7 Follow-up: F14, F52	Exper:	12	2	2	4	66	100	10	.011
	Contr:	0	1	6	13	14	100		
Phenomena which explicitly mention the Holy, Sacred, and Divine									
7 Post-drug: P57, P60, P61, P62, P77, P82, P83	Exper:	28	8	9	25	145	280	9	(.09)
	Contr:	0	17	33	20	111	280		
6 Follow-up: F15, F30, F40, F48, F50, F51	Exper:	31	3	10	16	170	300	9	(.09)
	Contr:	3	9	24	24	85	300		

The explicit items are more conventionally "religious," while the implicit items are more representative of the basic phenomenology of the "holy" described by Rudolf Otto.[3] Both explicit and implicit are examples of the category of sacredness as defined by our typology. The experimental subjects in our experiment experienced more implicit phenomena than did the control subjects. The phenomena of this category that the controls did experience were mainly explicit (see distribution of scores in the tables). Such an occurrence could have been expected, because the experiment was conducted with a worship service for setting and on a day particularly meaningful for Christian theological students who were the subjects. This could explain the lack of significant difference in the content-analysis data.

There were examples of the sense of sacredness in the content-analysis data, in both experimentals and control subjects, as the following excerpts show:

> *Experimental* Subject RM:
>
> > My eyes began to water and there was a wholesome beauty as I massaged the soft fleshy eyebags in my tears. I strained to fall on my knees with the meaningfulness of my younger days in lower school. My cowardliness was finally overcome and true humility ensued. The organ music blended beautifully and the scripture reading was the chorus of angels in bass clef.
>
> *Experimental* Subject GP:
>
> > I began the service with a feeling of intense devotion, and another strange, detached feeling… I directed my thoughts to the Passion Story, and saw Christ carrying his cross in a procession. Someone stepped in to help him, then I stepped in, too.
>
> *Experimental* Subject KR:
>
> > Rev. X's voice and manner set a definite mood in me. He was at one with the total experience of the divine and holy in that chapel.

---

[3] *Idea of the Holy*, pp. 24-35.

Control Subject IA:

> My first reaction to the chapel was its appropriateness for inducing a religious experience. The altar display, the darkness, and the solemness of the congregation, were immediately for "getting in tune with God." Later Rev. X's penetrating voice, combined with his very meaningful prayers and devotions, brought me to a spiritual height for the week.

Control Subject BL:

> I immediately began to meditate and pray and read my New Testament - I Cor. 13 ... I thought about the possibility of exploring new dimensions of one's self, and I prayed for God through Christ to be Lord of this dimension of being, for certainly no dimension of reality escapes His jurisdiction. Although I was curious about the experience of others around me, yet I was more concerned with my own private worship.
> When we entered the chapel, I began to pray for forgiveness and to praise God for the blessings of life. Although I did look around me on occasion, yet I found myself very much able to concentrate on my own private worship-service. As the organized service began, I found myself calmly participating in the richness of its structure. Often I would drift off into my own private prayer and devotional response, yet I was very able to find meaning in the long passages of prayer and poetry which I did hear. It seems that I was able to escape the distractions which usually hamper corporate worship, and to "lose myself" in the dimension of the religious. When interruptions did occur in my concentration, I did regain a certain intellectual curiosity, yet it lasted for only short durations of time. I easily re-entered the world of prayer and communion. ... In speaking of the worship service itself, I must stress that God seemed very close to me at this time. I found myself freed from the intellectual and conceptual dimensions of myself, to a large extent, and able to plunge into the emotive-intuitive dimension where my response was often that of "listening" to God. Very seldom were my conscious prayers "forced" in any way; rather, they followed naturally from "listening."

Control Subject MC:

> The chapel service was a meaningful one for me. ... Though the religious service was meaningful ... I cannot remember what Rev. "X" said, only what he did. He did move me, I remember, especially in his Scriptural readings. I was able to feel being with Christ. Christ stood out to me as he has only a few times before.

Control Subject NJ:

> As to the meaningfulness of the service - well, here goes. At first, the service became as any prior service. Then Rev. "X" caught me up into the real power and life of it (was he tremendous!).

Item P63, "sense of absence of anything that was felt to be holy, sacred, or divine," was *not* significant (*p* equal to .35). This is also indirect support for the conclusion that some degree of sacredness was experienced by both experimentals and controls.

The evidence has indicated, however, that sacredness was experienced more by the experimentals than by the controls, particularly the implicit type of phenomena, of which *awe* was an outstanding example. But from the lack of significance in the content-analysis data (*p* equal to .37), and the borderline significance of the combined follow-up data (*p* less than .055), we hesitate to conclude that sacredness was experienced by the experimental subjects in the most intense and complete way as defined by the mystical typology. That there was significant implicit phenomena in the experience of experimental subjects who had psilocybin has been demonstrated.

Category V: Objectivity and Reality

When all items which contributed to this category were combined, as shown in Table 20, *p* was not over .020 for any method of measurement. The distribution of scores showed a predominance of high scores for the experimentals, and "0's" for the controls.

All the items which contributed to this category are listed in Table 21 with the probability that the difference between scores of experimentals and controls was due to chance rather than to psilocybin. When individual items were examined, certainty of encounter with ultimate reality (P33, F17, and F70), intellectual illumination (P54 and F10), gain of some type of intuitive knowledge (P18, P23, F7, F27 and C11), increased capacity of mind (F4) and intensity and totality of the experience (P37, P38, P55, F5, F6, F38) all had significantly higher scores for the experimentals than for controls (*p* was less than .035 for each of these items). One item involving the retention of the certainty about the encounter with ultimate reality (P34) and one item involving intellectual illumination (P53) had *p* value of .062. This slight lack of significance was counterbalanced by the five other items measuring the same specific phenomena with *p* values all less than .035. Item F3 (certainty of the reality of the experience was also significant at the .02 level, but was not listed as essential because a reality other than ordinary reality is not specifically mentioned. Most controls, in fact, rated this item as "4" ("strong" - similar to other strong experiences of reality), and most experimentals rated is as "5" ("very strong" - stronger than ever before in my life). Other individual items which were not significant were: seeing symbolic meanings (P1), knowing everything (P4), knowledge of personal immortality (P24), communion with ultimate reality (F23), and psychological insight (C12). All these items received some scores from the experimentals but not enough to show a significant difference from the controls. P1, P4, and P24 are clearly supplementary when compared to the *a priori* definition of the category, and not essential. C12 compared to C11 showed that the intuitive insight gained through the experience was regarded by the experimentals as more philosophical-religious than personal-psychological.

When these 18 individual items which were significant were analyzed most rigorously by only counting the "strong" level scores, the *p* values of P54, P18, P23, P55, F7, and C11 rose to .063. For the other 12 items, *p* remained less than .035.

A more precise analysis of this category, however, was obtained when those items which corresponded most closely to the *a priori* definition of the category from the typology were combined separately. These items have been listed under the subcategory "most essential phenomena." As shown in Table 20 these basic items as a group were significant at the .02 level for all methods of measurement. The total scores and frequency distribution of scores followed the same pattern as did the combined scores in the same table.

Seven out of ten of these essential items were significant (*p* less than .035) and five of these seven remained significant when only "strong" scores were used (*p* less than .032). Of these five most important items, four were from the follow-up data after six months; one (P33) was from the post-drug data. Even under this most rigorous analysis, all of the rest of these ten items were almost significant (*p* less than .063). Item C11 from the content-analysis data (insights from being and existence in general) was in this last group. This loss of significance for the content-analysis data raises some doubt as to the completeness of the category as experienced by the experimentals. Individual item F70, however, was very strong evidence for this category because it measured after six month the *retention* of the certainty that ultimate reality had indeed been encountered (significant at the .032 level when only "strong" scores were used).

TABLE 20
Category V: OBJECTIVITY AND REALITY

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics

	Contr:	0	0	1	19	1	60		

The content-analysis material itself illustrated this category, as the following examples show:

Experimental Subject HQ:

> I felt I was at the real level of being.

Experimental Subject QX:

> I finally determined the truth was in man and that all his seeking was in vain and absurd, for it was not ultimately important what man knew intellectually but rather that he was at one with himself and his fellow man, i.e., in harmony and unity and love with mankind. ... Everything seemed to be more real and purposeful than I had ever known before.

(Comment: These two examples indicate the basic distinctions between "ultimate" reality and "ordinary" reality.)

Experimental Subject FK:

> Of first significance was the feeling of a profound religious "call" - the first I think I have ever really had. Before, I just felt as if I should enter the ministry, but now I "know" that I must. ... up to this time, I have never known the real meaning of the Christian truth - I have overintellectualized it, and have not involved myself in its eternal meaning and significance.

(Comment: This example also has strong overtones of the category "sense of sacredness.")

Experimental Subject FK:

> I would most emphatically emphasize this: I was helped in the liberation of previously repressed or inhibited areas of my life. That which was just a conception, was now made real. I had realized that one of my problems was now made real. I had realized that one of my problems was my far-reaching egocentricity - for the first time, I truly felt it, in the whole of my being.

Experimental Subject KR:

> The experiences are not unpleasant which confirms my belief that the Self (Jung's term for the integrating principle in the collective unconscious) has been further released in me toward greater wholeness.

(Comment: The certainty of intuitive-psychological knowledge of self in the last two examples represented a very meaningful kind of ultimate reality for these subjects.

TABLE 21
LIST OF ITEMS USED TO MEASURE OBJECTIVITY AND REALITY

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Most essential phenomena:		
a. Post-drug data:		
P33 Sense of certainty or conviction of encounter with ultimate reality (in the sense of being able to "know" and "see" what is really *real*) at the time of the experience:	.020	.020
P34 Sense of certainty or conviction of encounter with ultimate reality (in the sense of being able to "know" and "see" what is really *real*) now (in looking back):	(.062)	(.062)
P53 Intellectual illumination:	(.062)	(.063)
P54 Retention of such illumination after the experience:	.008	(.063)
b. Follow-up data:		
F27 Gain of insightful knowledge experienced at an intuitive level:	.004	.004
F17 Certainty of encounter with ultimate reality (in the sense of being able to "know" and "see" what is really *real*):	.008	.016
F70 You are convinced now, in retrospect, that you encountered ultimate reality in your experience (i.e., that you "knew" and "saw" what was really *real*):	.016	.032
F10 Intellectual illumination:	.035	.032
F23 Communion with ultimate reality:	(.227)	(.227)
c. Content-analysis data (2 items):		
C11 Insights into being and existence in general:	.004	(.063)
C12 Insights into personal finite self:	(.11)	(.25)
(2) Supplementary phenomena:		
a. Post-drug data (8 items):		
P37 Intensity of the response to ultimate reality:	.004	.008
P38 Totality of the response to ultimate reality:	.016	.016
P55 Sense of being grasped and dealt with:	.004	(.063)
P18 Sense of having known the universe in its wholeness:	.016	(.063)
P23 Sense of ultimate goodness as the basis of reality:	.035	(.063)
P24 Intuitive knowledge of your immortality:	(.11)	(.11)
P1 Seeing symbolic meanings of things:	(.18)	(.18)
P4 Feeling of being very wise, knowing everything:	(.23)	(1)
b. Follow-up data (6 items):		
F5 Intensity of your response to the experience:	.001	.001
F6 Totality of the response to the experience:	.001	.001
F38 Sense of being grasped and dealt with by the experience:	.001	.002
F4 Enhanced capacity of mind:	.008	.008
F7 Sense of having known the universe in its wholeness:	.016	(.063)
F3 Certainty of the reality of what was experienced:	.020	.020

The evidence taken together certainly indicates that phenomena corresponding to that described in our typology did occur and to a marked degree in the form of most essential elements as well as some supplementary ones. The lack of consistency, however, in all three methods of measurement when only "strong" scores were analyzed makes not fully certain the conclusion that the experimentals experienced the most complete form of this category.

We thus conclude that the phenomena described by the category "objectivity and reality" did occur significantly more in the experimentals who received psilocybin than in the controls who did not, as judged from analysis of the essential items alone as well as in combination with the supplementary ones. Evidence showed that the experience of this category was very close to, but not quite identical with, the most complete form of the mystical typology.

Category VI: Paradoxicality

As seen in Table 22, the experimentals scored significantly higher than the controls in the phenomena of paradoxicality for all three methods of measurement (*p* less than .004). The experimentals had more "strong" ratings than the controls, as demonstrated by the frequency distribution of scores. In other words, there are only four chances in 1000 that this difference between experimentals and controls was not enhanced by psilocybin.

TABLE 22
Category VI: PARADOXICALITY
Combination of All Items

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items	**(*n*=10)**	**Strong**	**Moder.**	**Slight**	**None**	**Actual**	**Maximum**	***N***	***p***
4 Post-drug: P65, P68, P72, P73c	Exper:	24	4	5	7	116	160	9	.002
	Contr:	1	2	4	33	17	160		
3 Follow-up: F73, F25, F33	Exper:	10	0	4	16	51	150	8	.004
	Contr:	0	1	1	28	4	150		
1 Content Analysis: C13	Exper:	6	2	2	0	24	30	10	.001
	Contr:	0	0	0	10	0	30		

All phenomena which were used to measure paradoxicality are listed in Table 23. All individual items were significant at the .016 level except F73. The interviews revealed the reason for this apparent discrepancy. The wording of this item made the statement untrue for most subjects because of the words, "You have been accused." Subjects who later were found to be experimentals stated that they had not been *accused* of logical contradiction because they had not even tried to describe their experience to someone who would be unsympathetic enough to accuse them of such contradiction. These subjects readily admitted the difficulty of being strictly logical in descriptions of their experience. The content-analysis data and other items which are paradoxical even in their description did show significant differences from the controls even when only the "strong" scores were used (*p* less than .032). Paradoxicality was also supported implicitly by item P64, the converse of item P65. Item P64 stated that "the experience is describable by logical statements which are not contradictory" and did not show a significant difference between experimentals and controls (*p* equal to .35).

TABLE 23
LIST OF ITEMS USED TO MEASURE PARADOXICALITY

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug data (4 items):		
P65 Sense that an attempt to describe the experience in logical statements becomes involved in contradictory language:	.016	.063
P68 Paradoxical dissolving of the subject-object dichotomy in spite of the empirical multiplicity of objects (they are still perceived as separate):	.008	.016
P72 Paradoxical transcendence of space as defined in 68-71:	.004	.008
P73 Pure awareness with no empirical distinctions (i.e., one is beyond the self-consciousness of sense impressions, yet one is not unconscious):	.002	.008
(2) Follow-up data (3 items):		
F73 You have been accused of logical contradiction in trying to describe the meaningfulness of your own experience to others who were not present:	(1)	(1)
F25 Loss of feelings of difference from objects:	.016	.032
F33 Fusion of the self into a larger undifferentiated whole:	.008	.032
(3) Content-analysis data (1 item):		
C13 Paradoxicality:	.001	.016

Experimental Subject QX:

> Everything was part of the other, yet distinct in itself.

(Comment: This is an example of external unity as well as paradoxicality.)

Experimental Subject GP:

> In fact, I'm not sure I have one over-riding impression, unless it is one of a confused kind of clarity.

Experimental Subject TD:

> I had a vision in which the flowing colors seemed to be me. It was infinity, with many timelines running through it. ... I decided then that words were adequate to describe the experience, but only if you could describe each tributary, and say the words all at once.

(Comment: The description is not only paradoxical but is also an example of the next category, alleged ineffability.)

From the consistency of statistical evidence from all methods of measurement we conclude that the experimentals who got psilocybin experienced the phenomena of paradoxicality to the most complete degree defined by this category in our typology of the mystical consciousness.

Category VII: Alleged Ineffability

As seen in Table 24, the experimentals scored significantly higher than the controls in this category for all three methods of measurement (*p* less than .008). The experimentals had more strong ratings than the controls, as demonstrated by the distribution of scores.

TABLE 24
Category VII: ALLEGED INEFFABILITY
Combination of All Items

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items	**(*n*=10)**	**Strong**	**Moder.**	**Slight**	**None**	**Actual**	**Maximum**	***N***	***p***
1 Post-drug: P66	Exper:	5	3	2	0	33	40	8	.004
	Contr:	0	4	3	3	16	40		
3 Follow-up: F16, F57a, F92	Exper:	22	5	1	2	115	150	10	.001
	Contr:	1	3	6	20	22	150		
1 Content Analysis: C14	Exper:	2	1	4	3	12	30	7	.008
	Contr:	0	0	0	10	0	30		

All phenomena which were used to measure alleged ineffability are listed in Table 25. All individual items were significant at the .008 level and most were even more significant than this. Alleged ineffability was also supported indirectly by the nonsignificance of item F57b, "the *ease* of communication of your experience," which was the converse of F57a. When only the "strong" scores were used, all individual items remained significant (*p* less than .032) except for the content-analysis data. These were, in fact, a sparsity of statements in the accounts which explicitly stated the difficulty of describing the experience. Perhaps this was due to the fact that the subjects were at the time actually describing their experiences as best they could. Implicit allusions to this phenomenon were more frequent.

Some of the best examples from the content-analysis data of those who had psilocybin are as follows:

Experimental Subject TD:

> I imagined I heard someone describing or explaining our experience, and I wanted to object because they were lying. And yet I felt that it was all that could be said. Somehow it was theological ideas they were messing up, yet I could understand that these lies were the best we could do. But they *were* lies, and that was important, too.

Experimental Subject KR:

> During this time the sense of "we-ness" became a sense of oneness with what I can only describe as "Logos" or a personal Word... (Theological terms were given great meaning in this experience but are totally inadequate in describing the depth and impact of it.)

(Comment: This was also the beginning of the phenomenon of internal unity for this subject.)

Experimental Subject FK:

> I cannot describe the sense of the Divine - He was the eternal mystery that *was*: He was everywhere, but completely transcendent; the Divine, truly not of this world, but whose message had the greatest significance for this world. I felt compelled to go to the front of the chapel, to minister in the name of Christ - for no one else was doing it, and it *had* to be done... For really the first time, I realized that man cannot challenge and try to limit God to a conceptual system: it is God who challenges men to do His will. God is, and that is all one can say. I am human; I will still try to build an elaborate theological system, for my egocentric gratification, and also to be able to communicate with others. (I am not saying that intellectual theology is bad, but that it is so completely inadequate to interpret the Divine.)

(Comment: This is an example not only of alleged ineffability but expresses the sense of sacredness as well. The reality which he felt is an example of the category: Objectivity and reality.)

TABLE 25
LIST OF ITEMS USED TO MEASURE ALLEGED INEFFABILITY

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug data (1 item):		
P66 Sense that the experience cannot be adequately described in words:	.008	.032
(2) Follow-up data (3 items):		
F16 Feeling that you could not do justice to your experience by a verbal description:	.001	.016
F57a You have had difficulty in trying to communicate your own experience to others who were not present:	.002	.032
F92 You now feel that the meaningfulness of your own experience is beyond words:	.004	.016
(3) Content-analysis data (1 item):		
C14 Ineffability:	.008	(.25)

We therefore conclude that the experimentals did experience the phenomenon of alleged ineffability to a considerable degree - certainly sufficient for inclusion as an example of this category as defined by the mystical typology but not in the most intense way possible. In other words, the psilocybin experience under the conditions of this experiment can be concluded to closely resemble this aspect of mystical experience.

Category VIII: Transiency

As seen in Table 26, when the scores of all items were combined, the experimentals scored significantly higher than the controls for all methods of measurement (*p* less than .004). The frequency distribution of scores demonstrated the predominance of high scores for the experimentals and scores of "0" for the controls. In other words, there are only four chances in a thousand that the phenomenon of transiency was not due to psilocybin.

TABLE 26
Category VIII: TRANSIENCY

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items	**(*n*=10)**	**Strong**	**Moder.**	**Slight**	**None**	**Actual**	**Maximum**	***N***	***p***
Combination of all phenomena:									
6 Post-drug: P12, P26, P27, P28, P30, P31	Exper:	34	11	7	8	180	240	10	.001
	Contr:	0	1	7	52	12	240		
4 Follow-up: F8, F9, F52, F86a	Exper:	27	8	3	2	151	200	10	.001
	Contr:	1	4	1	34	17	200		
1 Content Analysis: C10	Exper:	8	1	0	1	26	30	8	.001
	Contr:	1	0	0	9	3	30		
Essential phenomena:									
2 Post-drug: P30, P31	Exper:	8	6	3	3	56	80	9	.002
	Contr:	0	0	2	18	2	80		
2 Follow-up: F52, F86a	Exper:	11	8	0	1	70	100	9	.002
	Contr:	1	2	0	17	10	100		
1 Content Analysis: C10	Exper:	8	1	0	1	26	30	8	.004
	Contr:	1	0	0	9	3	30		

All the items which were used to measure transiency are listed in Table 27 in two groups: essential and supplementary phenomena. When scores were used in the analysis, all individual items showed a significantly higher score for experimentals than for controls at the .004 level except for suddenness of appearance which was still significant at the .02 level. Under the most rigorous analysis using only "strong" scores, most of the essential items which directly defined transiency as such, remained significant (*p* less than .032) except for F31 and F52. It was interesting that these last two items are consistent because they would indicate that the lighter levels of unusual consciousness (F31) were the ones which did not disappear completely by the next day. Such an "afterglow effect" was confirmed during the interviews. All items which directly measured suddenness remained significant under the most rigorous analysis (P27, F28, and F9), as did those which indicated a change in usual consciousness, P26 and F8 (*p* less than .020 for all these items). The only other item which did not remain significant (*p* less than .13) when only the "strong" scores were used was the experience of several levels (of consciousness) at once (P12) which was not so closely related to transiency as the other items.

Other substantiating evidence that the experimentals experienced change from usual consciousness was item P29 (stability of level of consciousness *during* the experience) which was significant for the controls (*p* less than .035).

Examples of transiency from personal accounts of two experimentals are presented below as further evidence:

Experimental Subject GP:

> ... after I was quite completely "out" of the experience, talking with my group and eating an apple...

Experimental Subject QX:

> At this point, the service had come to a close, and I was beginning to lose the full strength of my experience.

TABLE 27
LIST OF ITEMS USED TO MEASURE TRANSIENCY

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Essential phenomena:		
a. Post-drug data (2 items):		
P30 Transiency of duration of deepest levels:	.002	.032
P31 Transiency of duration of levels other than the deepest:	.004	(.13)
b. Follow-up data (2 items):		
F52 Return to you usual state of consciousness day after the experience:	.002	(.063)
F86a You have lost by now the state of consciousness you experienced on Good Friday:	.004	.016
c. Content-analysis data (1 item):		
C10 Transiency of unity:	.004	.008
(2) Supplementary phenomena:		
a. Post-drug data (4 items):		
P26 Appearance of various levels of consciousness:	.001	.002
P27 Suddenness of appearance of various levels of consciousness:	.002	.004
P28 Suddenness of disappearance of various levels of consciousness:	.004	.016
P12 Being able to operate on several levels at once:	.004	(.13)
b. Follow-up data (2 items):		
F8 Definite change in your usual state of consciousness:	.002	.002
F9 Suddenness of appearance of various dimensions of consciousness:	.020	.020

For more precise analysis, the items most essential to the definition of the category were analyzed as a group separately from those items which were only closely related. As seen in Table 26, the results in terms of total scores, score distribution, and significance level, followed a pattern similar to that of the combined scores of all the items (*p* less than .004 for all subcategories).

The most important individual item was F86a because here the return to usual consciousness was measured after six months rather than after a few days. The experimentals had significantly more "strong" scores than the controls (*p* less than .016).

The closely related items were really a prerequisite for the essential ones, because a return to usual consciousness would not be relevant if there had been no change during the experience. The most specific item in this regard is from the content-analysis data. C10 represents the whole category because this distinction between "during" and "after" the experience was explained. Judges were told to score evidence of transiency of unity - a basic phenomenon of the mystical typology.[4] The fact that this item remained significant under the most rigorous analysis confirms the conclusion from the rest of the data that the phenomena of transiency indeed were experienced more by the experimentals than controls, and to the most complete degree in the typology. In other words this phenomenon was induced by the ingestion of psilocybin under the conditions of this experiment.

Category IX: Persisting Positive Changes in Attitude and Behavior

As seen in Table 28, the experimentals scored significantly higher than the controls for both methods of measurement, when all items were combined which rated persisting positive changes, compared to the subjects' condition before the experiment (*p* less than .001 for followup data, and less than .002 for content-analysis data). The frequency distribution of scores indicated that there was a predominance of "strong" scores for the experimentals, and "0's" for the controls. The individual items which measured this category were listed in Table 29 in four subcategories: (1) changes toward self, (2) changes toward others, (3) changes toward life, and (4) changes toward the experience.

---

4. See instruction manual in appendix E under "transiency of unity."

TABLE 29
LIST OF ITEMS USED TO MEASURE PERSISTING POSITIVE CHANGES IN ATTITUDE AND BEHAVIOR

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Toward Self:		
a. Follow-up data (11 items):		
F55b You have more personal integration:	.002	(.063)
F58b Your behavior has changed in ways you would consider positive since the experience:	.002	(.063)
F63a You have a greater sense of inner authority in your life:	.002	.032
F64b Your life has a heightened dynamic quality:	.008	(.063)
F74b Feelings of anxiety have decreased:	.016	(.25)
F87a You have more joy in your life:	.016	(.25)
F77b You are more creative person:	(.062)	(.25)
F61b Feelings of depression have decreased:	(.063)	(.25)
F66b You have increased feelings of happiness:	(.11)	(.25)
F69b You have more peace in your life:	(.11)	(.25)
F71b You have an increased achievement efficiency:	(.50)	(1)
b. Content-analysis data (1 item):		
C15 Changes toward self after six months:	.004	.008
(2) Changes toward others:		
a. Follow-up data (7 items):		
F54a You have become more sensitive to the needs of others:	.002	.032
F60b You are more your true self with others:	.008	.032
F91a You are a more authentic person:	.016	.032
F85b You now feel more love toward others:	.016	(.063)
F68a You are more tolerant toward others:	.032	(.063)
F76a You have a more positive relationship with others:	(.063)	(.063)
F65b Others have remarked about a positive change in you since Good Friday:	(.19)	(.19)
b. Content-analysis data (1 item):		
C17 Changes toward others after 6 months:	(.812)	(.812)
(3) Changes toward life:		
a. Follow-up data (15 items):		
F53a The experience has changed your philosophy of life positively:	.001	.032
F89a Time spent in quiet meditation has increased:	.008	(.25)
F83b You spend more time for devotional life:	.008	.032
F62a Your appreciation for life has increased:	.002	(.13)
F82 You feel you now know a new dimension of life:	.004	.032
F81b Your life has more richness:	.020	(.13)
F67a Your life has more meaning:	.035	(.063)
F79a Your sense of values (i.e., what is important to you in life) has changed positively:	.035	(.13)
F59a You now feel a greater need for service for others:	.035	(.13)
F84a Your appreciation for the whole of creation has increased:	.035	(.063)
F95 You now feel your life has taken a definite change of course because of this experience:	.032	(.13)
F72a You have an increased sense of reverence:	(.062)	(.063)
F78a You have more enthusiasm for life:	(.062)	(.13)
F75b You now have a more certain vocational commitment:	(.063)	(.063)
F93b You have more of a sense of the adventurous outreach of life:	(.09)	(.09)
b. Content-analysis data (1 item):		
C19 Changes toward life after six months:	.016	.016
(4) Changes toward the experience:		
a. Follow-up data (5 items):		
F56a You learned something useful from the experience:	.004	.032
F94a Your experience has been valuable for your life:	.020	.020
F96 You have tried to recapture any parts of the Good Friday experience since then:	(.15)	(.15)
F98a You would be interested in repeating the same experience you had on Good Friday:	(.26)	(.26)
F99a You would be interested in having more of these kinds of experiences (not necessarily with the hope of an exact repetition of your Good Friday experience):	(.23)	(.23)
b. Content-analysis data (1 item):		
C21 Changes toward the experience after six months:	(.5)	(.5)

Changes toward self

Seven out of the twelve items which represented persisting changes toward self, were significant below the .016 level. These items indicated a definite positive change in both behavior (F58b) and attitude in terms of better inner functioning - e.g., increased personal integration (F55b), inner authority (F63a), dynamic quality (F64b), and joy (F87a); and decreased anxiety (F74b). Increased creativity (F77b) and decreased depression (F61b) were almost significant (*p* less than .063). When only "strong" scores were used, inner authority (F63a) remained significant (*p* less than .032), and F55b, F58, and F64b had higher scores for experimentals than for controls but just above the .05 level of significance (*p* less than .063).

Changes toward others

Five out of the seven items which represented changes toward others were significant (*p* less than .032). These items indicated a definite positive change in interpersonal relations in terms of more sensitivity (F54a), authenticity (F60b and F91a), tolerance (F68a), and love (F85b). More positive relationships with others (F76a) was almost significant (*p* less than .063). Of these five most significant items, three remained significant at the .032 level when only "strong" scores were used. These most important items were the phenomena of more sensitivity and more authenticity in being one's true self with others (F54a, F60b, F91a).

Changes toward life

Thirteen out of the 17 items which represented changes toward life were significant at the .035 level. Increased sense of reverence (F72a), vocational commitment (F75b), and enthusiasm for life (F78a), were only significant at the .063 level. Of the 13 most significant items, the four most important, as indicated from "strong"-score analysis were: positive change in philosophy of life (F53a), knowledge of a new dimension of life (F82), and increased sense of the preciousness of life (F90b) - *p* less than .032: increased meaning (F67a), sense of reverence (F72a), vocational commitment (F75b), and appreciation for creation (F84a) were significant under such analysis only at the .063 level.

Changes toward the experience

Two of the six items which represented persisting changes toward the experience were significant at the .020 level: learned something useful (F56a) and considered the experience valuable (F94a). These differences between experimentals and controls also remained significant when only the "strong" scores were used (*p* less than .032 for both items).

As shown in Tables 30-33, the combined scores for the subcategories, changes toward self and toward life, were significant for the experimentals from both methods of measurement (*p* less than .016). The total scores and score distribution from these two subcategories were consistent with those of the combined scores of all items in the category (predominance of "strong" scores for experimentals and "0's" for controls). While the other two subcategories, changes toward others and toward the experience were significant from the follow-up data (*p* less than .001 for others and less than .055 for the experience), there was no significant difference between experimentals and controls in the content-analysis data (*p* greater than .19).

	Contr:	0	0	0	10	0	30		

Both the follow-up accounts were designed to measure negative as well as positive changes. The positive items discussed above had their negative counterparts, but the only individual items significant below the .01 level were F74a, increased feelings of anxiety (*p* less than .032), and F61a, increased feelings of depression (*p* less than .63). When only "strong" scores were used, neither of these items remained significant (*p* greater than .5). Some ambiguity existed, however, because the positive expressions of both these items (F74b and F61b) were at least, if not more, significant than the negative. These two negative items belong to the subcategory "changes toward self," which tended toward significance (*p* = .062) in the follow-up data for this subcategory as a whole, but was clearly not significant in the content-analysis data. None of the negative subcategories showed a significant difference between experimentals and controls, at the .05 level, from either method of measurement. (See Tables 30-33.) The total negative scores of these categories were relatively low in relation to the number of items represented, and the score distribution was predominantly at the low end of the scale - almost entirely "0's" for both experimentals and controls. The positive changes far outbalanced in number and intensity the few and relatively moderate negative changes reported.

Some examples of persisting positive changes from the content-analysis data are as follows:

Changes toward self:

Experimental Subject HQ:

> Very strongly beneficial: I have had a much greater degree of self-realization since Good Friday. By this I mean a greater certainty of being and becoming. Closely connected with this is the feeling of being a creature of purpose.
> I feel that I have a greater realization of my motives that lie behind my various actions. I do believe I have an awareness of the selfishness that underlies many of my actions. This realization has been met with attempts to cast this selfishness aside to go beyond it.
> I have made reference to the joy I experienced when I came back to life since the Good Friday afternoon experience. At times I have felt a joy of being alive and having real existence. I do not believe I have ever experienced it previous to Good Friday to the degree I did then or to the degree I have since, even though I intellectually knew of it.

Experimental Subject GP:

> Very strongly beneficial: Expanded awareness of myself. Regularly, in introspection, occasionally spontaneously, I recognize dimensions of my life that I had not known before: longings, goals, abilities, kinds of strength.

Changes toward others:

Experimental Subject TD:

> Strongly beneficial: Increased willingness, though not necessarily ability, to see interpersonal relations from the side of the other person. An increased insight into interpersonal relations.

Experimental Subject FK:

> Strong benefit: A startling sensitivity to others - especially to those with "problems".

Changes toward life:

Experimental Subject FK:

> Very strong benefit: A sense of "call" - insofar as this means that the Word must be proclaimed to the "world" - not so much verbally as "existentially", and that somehow I must respond to this challenge, as it has appeared to me.

Changes toward the experience:

Experimental Subject EB:

> Moderately beneficial: An appreciation of and ability to enter in a limited way into experiences dealing with that beyond one's usual consciousness (two aspects of which are "mystical" elements and "unconscious" elements).

Experimental Subject FK:

> Very strong benefit: A profound recognition of the role of the "mystical" in the full religious life - but this attitude seemed not as an escape from the world, rather giving me a greater sense of concern for the here and now.

Experimental Subject RM:

> Very strongly beneficial: Strong desire for prayer, communion with God, and time in the "wilderness".

Experimental Subject KR:

> Strongly beneficial: Aid in spiritual growth.

A significant difference between experimentals and controls in persistent positive changes after six months in all four subcategories has been demonstrated by these data. The most significant subcategories were changes toward self and changes toward life. The most important changes were those due to strong scores, as has been suggested. Changes toward others and toward the experience, occurred in both the experimentals and the controls, as seen from the total scores of these subcategories. Perhaps the interaction with the experimentals was a factor in these results, as is suggested by the following quotes from three controls:

Control Subject NJ:

> The entire day was meaningful - helped to draw friendships tighter and added much meaning to my religious life. ... Reverend "X", FK, and his entire activity (including playing "Jesus Christ is Risen Today"), and the talks afterward, were contributors to an extremely meaningful experience.

Control Subject IA:

> It was one of the most exciting days of my life. The fellowship with the students, and particularly with all of the wonderful group leaders, was very meaningful.

Control Subject JN:

> I was very glad to have been able to be part of the experience; for the first time I was really able to talk in depth with RM and TD.

(Comment: RM and TD were the experimentals in JN's group.)

The conclusion can be drawn that in terms of certain changes toward self and changes toward life, the drug experience is similar if not identical with changes resulting from mystical experiences as defined by our typology. This conclusion is not as certain for changes toward others and toward the experience because of lack of confirmation from content-analysis data, although specific items, as well as these subcategories as a whole, were strongly significant in the followup data.

Other Data

Items which were not directly applicable to categories of our typology of mysticism are listed in Appendix G, in four main groups:

I. Integrative and constructive phenomena.
II. Disturbing changes in attitude and behavior.
III. Physical sensations.
IV. Miscellaneous.

The significance level of the difference in scores between experimentals and controls was given both when all scores were counted and also when only "strong" scores were used. This information, while interesting, does not contribute directly to the argument presented above.

I. Integrative and constructive phenomena:
The most striking phenomena under this grouping were the death-rebirth experiences during the experiment (significant at .032 level), which may have helped foster the lasting sense of new significance and meaning to life.

II. Disturbing changes in attitude and behavior:
Almost all of these phenomena which showed a significant difference between experimentals and controls, took place *during* the experience. In the six-month follow-up questionnaire, as has been shown above, only increased anxiety was significant below the .05 level, and this was not due to "strong" scores. Nine out of ten of the experimentals gave a positive evaluation to their experiences as a whole, in spite of the occurrence of some negative elements, of which transient fear was the most striking, as shown in the following examples from the content-analysis:

> *Experimental* Subject FK:
>
> > Afterwards (by that, meaning Saturday and somewhat Sunday), I did have a distinct negative feeling beside the much, much stronger feeling of having been through a most meaningful, deep and significant experience. I would like to sincerely thank you for making this opportunity available for me... and I am sure it will have positive and creative effects on my "quest for realization" as I integrate the insights which were gained.
>
> *Experimental* Subject DT:
>
> > Despite the fear and negative attitude when I was in that one violent and painful dream, my reaction to the whole experience was a positive one, and I think I should like to do it again.

The relation between mysticism and phenomena generally considered as psychopathology is an interesting one which needs further elucidation and research, but is beyond the scope of this dissertation.

III. Physical phenomena:
The variety of physical sensations, especially visual, which accompanied the drug experiences, were interesting and could be compared to the equally diverse physical manifestations reported by the mystics, but again, such a comparison was not the chief area of interest of this research. It is noteworthy that no experimental subject became preoccupied with negative physical phenomena such as dizziness or vomiting, although transient nausea was experienced (p less than .008). This result may have been due to the lack of emphasis on physical phenomena in the preparation of the subjects. The controls had significantly higher scores than the experimentals on the sensations of warmth and itching (P115 and P116) at the .035 level. These scores reflected the effectiveness of action of nicotinic acid on the controls.

IV. Miscellaneous:

There was 100% agreement among experimentals and controls as to who got psilocybin, as shown by the score difference between experimentals and controls on P128, F100a, and F100b, when only "strong" scores were used (*p* less than .001).

Chapter VII
GENERAL DISCUSSION AND CONCLUSIONS

Discussion of Design

Alternate ways of designing the experiment were considered. Subjects could have been told nothing other than that they were going to participate in a psychological experiment with drugs in a non-religious setting. The presupposition, however, that set and setting are very important led to the use of techniques which would encourage a serious and expectant attitude, group support, a trustful atmosphere, and security for the subjects who, it was hoped, would have meaningful experiences. Everything possible was done to discourage the development of fear, suspicion and mistrust. The chapel as setting; theological students as subjects; and the religious focus in preparation, expectation, and implementation were deliberate for maximum encouragement of "religious or mystical" phenomena, because these were what we wanted to study. To control for so much positive suggestion double-blind procedure was employed for an experimental and control group.

The psychedelic drug experience is so unique and powerful that the double-blind control design would have been completely meaningless if the subjects had known what to expect from previous experience for they would have certainly known whether or not they received the drug.[1] In our study double-blind technique was initially effective because none of the twenty subjects had ever had an experience before with LSD, psilocybin, or mescaline. In spite of this fact by the time the chapel service was over all of the experimentals were certain that they had received psilocybin because of the profound changes from their usual state of consciousness. One purpose of the control group was to measure the effect of suggestion. Data from the tape recordings, written accounts, and interviews indicated that in the early part of the experiment positive suggestibility was greatly enhanced by the somatic effects of the nicotinic acid which the controls had all assumed was psilocybin. They had waited with eager anticipation for more effects. By the end of the chapel service, however, most of the control subjects were doubtful that they had received psilocybin, but were still uncertain because of the impact of the service combined with the initial somatic effects. The following excerpt from a tape recording which was made immediately after the service illustrates this fact:

> *Control* Subject MC:
>
> > Soon after swallowing the pill I noticed sensations of heat. Then I found myself in a very relaxed state... very free. After going into the chapel, time went very quickly. The service was very meaningful. ... Rev. "X's" voice seemed to have an effect on me. A times I felt like cheering and at other times like crying. His Bible readings moved me. I felt as if I were there for the first time and really experiencing these things, but at this time I honestly can't say whether I had the drug or not.

During the group discussions the qualitative difference in experiences became strikingly obvious to the participants. This created a bias in the controls, but their written accounts were remarkably similar to their tape recordings which were made after the service before the group discussions. Also the fact that the subjects had been told that some would not receive psilocybin made them curious as to their status and eager for any distinguishing sign. The nicotinic acid acted within ten to twenty minutes, but within an hour and one-half most of the physical affects had worn off. The psilocybin took from thirty minutes to one-and-one half hours to become noticeable. Two of the ten experimentals did not feel any effects until after the chapel service started. The possibility of giving the experimentals a combination of psilocybin and nicotinic acid to produce a similarity of initial somatic effects (e.g., flushing and itching of the skin) in both the experimental and control groups was considered but rejected because the possible antagonism between nicotinic acid and psilocybin was not known. Also, such initial physical effects might have focused the psilocybin experience on physical symptoms.

---

[1] Sherwood, Stolaroff, and Harman, *op. cit.*, p. 72.

Deception might have been used by telling the subjects that they all would receive psilocybin, but it was felt that such a design might have disturbed the atmosphere of trust and friendliness by arousing confusion and suspicion. Actually some deception was used because although the subjects had been told that some would not receive psilocybin, they had not been told that a control substance would be given. The controls had assumed that they would get a true placebo. Afterwards three control subjects expressed some resentment because of this assumption, but were still willing to cooperate in collection of data. Disappointment was a much stronger sentiment. During the interviews (including the one after six months) discussion of who might have been an experimental or control was discouraged. The experimenter emphasized the fact that he did not know who had received psilocybin and that there was a possibility of non-reaction to the drug. Most of the subjects, however, did not become less certain that they either received or did not receive psilocybin.

Obviously, a disadvantage of having the experimentals and controls mixed in the same session was that the behavior and experience of the experimentals had an effect upon the way that the controls evaluated their own experiences by giving them a clue as to their status. The mixed discussion period after the service would be subject to the same criticism only more so because the controls listened to others describe their experiences. The discussion period was designed to give group support and security to those recovering from the effects of the drug. The controls could not help comparing their experiences to those of their friends. Such a comparison would have been inevitable, however, because of the close-knit relationship of all the participants who attended classes together at the same school.

As an alternative procedure, the control group of matched subjects could have attended the same service (which could have been reproduced because it was taped) at a different time from the experimentals. Such a design, however, would have destroyed the double-blind feature, and the set and setting would not have been the same for both groups. The separate, although matched, experimental and control groups would have had to have been kept from communicating or even knowing about each other (perhaps by using students from different seminaries). The preparation and expectation would not have been quite the same. The natural effect of a Good Friday service would have been lost by having the reproduced service on two separate occasions other than Good Friday. With such a design the experimenter and leaders would have known which group was experimental and which was control after the first group had participated. The way the experiment was actually run, uniformity of set, setting, and suggestion was maximized. The experiment demonstrates the difficulties of double-blind technique in group sessions with such dramatic and powerful drug-induced effects in the experimental group.

Subjects might have been screened to find only those who had a particular mystical inclination or who had previously had experiences which closely resembled the mystical typology. Such persons might have felt more at ease in the drug situation, and perhaps their drug experiences might have been even closer to the mystical state of consciousness. Only four of the twenty subjects would have definitely qualified under such a criterion. These four were matched into pairs, and these two experimentals had some of the more strongly "mystical" experiences. As might be expected, their controls were the two who found the religious service most meaningful. To ding twenty such subjects might not have been possible at the same seminary and would heave required hundreds of hours of interviews. It was thought more instructive to see what would happen with a more representative sample within an already specialized group, all of whom were especially interested in religion.

Observations of the Experimenter during the Experiment

Although the main purpose of this research was to study the internal experience of the subjects, their external behavior during the experiment was also observed and recorded. In general the experiment ran smoothly, according to plan. Before the capsules were distributed there was a general tone of excitement, and eager yet serious expectation. During the first one-and-on-half hours, quiet was observed relatively unbroken in the groups. A few subjects felt the need to visit the men's room for natural purposes or for a smoke. Several subjects asked the experimenter for reassurance because of various somatic symptoms (such as heat or "feeling very strange"). Some were noticeably flushed. The majority sat quietly with their groups. When the time came to move into the chapel, only one subject who felt a little nauseated remained behind with his leader for a time.

The experimentals as a group stayed in the chapel for about 85% of the service compared to the controls who stayed for about 95%. During the first half of the service there was not much activity in or outside the chapel. For the last half more overt behavior occurred in the experimentals. A few went up to the altar. One entered the pulpit and sat at the organ in a symbolic way to express what he felt was a need for someone to lead the service. There were some spontaneous vocal exclamations and some weeping. A few lay down on the pews or the floor; most sat quietly throughout.

Most of the movement outside the chapel was to the men's room. One experimental subject wanted to sit quietly in one of the large rooms for about an hour. Only one subject was taken out of the service by his leader because he became too restless. The leader stayed with him for reassurance.

The leaders were especially helpful in making the experiment run smoothly. The ones who received psilocybin seemed to be entering into the experience much more fully. As leaders, there was no observable difference in effectiveness between the psilocybin and non-psilocybin group. Most of the experimental subjects did not need individual attention, but several later expressed appreciation for the reassurance afforded by the presence of experienced leaders. During the relaxed group discussions, there was more rapport between leaders and subjects who had received psilocybin than between those who had not. Not until after the service had begun did the leaders definitely determine which of their group members received psilocybin. In fact, there were a few initial wrong guesses.

In some cases, there was, after the service, a difference in appearance and behavior between experimentals and controls. Pupil dilation was an obvious physical sign. Experimentals were also more informally attired; ties had been loosened or removed, and hair was not combed. Their dominant mood was quiet detachment or joyful exuberance. They wanted to share the impact of their experience with their friends. Two had a little difficulty in readjusting to the "ordinary" world and needed special reassurance by their leaders until the drug effects subsided.

Summary and Discussion of Data

The data in general have indicated that the experimental subjects, who received psilocybin in the same setting and with the same preparation as the controls, had a statistically significant, *different* experience, as indicated by the higher scores on particular items and groups of items from the three methods of measurement.

These differences in terms of the phenomena of the categories defined in our typology of mysticism were presented in detail in Chapter VI. With the exception of sense of sacredness the combined scores of all items in every category were significantly higher for the experimentals than for the controls, by all three methods. As summarized in Table 34, the significance levels of these score differences were less than .02. The difference in sacredness was not significant only in the content-analysis data (*p* greater than .37). The conclusion from these data is that the persons who received psilocybin experienced to a greater extent than did the controls the phenomena described by our typology of mysticism. But a more rigorous analysis was needed to determine the degree to which these persons experienced such phenomena. As presented in Chapter VI and summarized in Table 35, when only the scores of the items most essential to the definition of each category were combined into more precise subcategories, the differences between experimentals and controls persisted, for the most part, in their significance (*p* less than .02). This finding adds weight to our initial impression from Table 34, but still does not answer the question of completeness.

The essential items which remained significant at less than below the .05 level when only "strong" scores were used, were the best indication of the *degree* of completeness or intensity to which the phenomena of the mystical typology had been experienced. In each subcategory the number and occurrence of such essential items from each method of measurement have been discussed above in Chapter VI. The results from the most important subcategories are presented in summary form in Table 35. The subcategories fell into three groups representing three levels of completeness or intensity on the basis of the empirical data.

[a] Not used for measuring this category.

The *first* group very closely approximated the most complete phenomenological expression of the mystical typology. From all methods of measurement, they had both statistically significant higher scores for the experimentals than for the controls (*p* less than .016), and essential items which remained significant after "strong" score analysis. These subcategories were: *internal unity*, *transcendence of both time and space*, *transiency*, *paradoxicality*, and *persisting positive changes in attitude and behavior* toward *self and life*. We conclude that these phenomena of the mystical typology were experienced in a rather complete way by the subjects who took psilocybin.

The *second* group of subcategories was considered almost but not quite equivalent to the maximum degree of intensity or completeness defined by our typology. They had statistically significant, higher scores for the experimentals than for the controls, from all three methods of measurement (*p* less than .020), and had some items which survived by the most rigorous application of the Sign Test from both questionnaire studies, but *not* from the content-analysis data. These essential subcategories were: *external unity*, *objectivity and reality*, *alleged ineffability*, and the most universal phenomena of *deeply felt positive mood* (*joy*, *blessedness*, and *peace*). It will be remembered from our analysis in Chapter VI that joy was the significant element in this last-mentioned subcategory and that peace and blessedness were experienced but not to a significantly higher degree by experimentals. Objectivity and reality had strong supporting evidence from supplementary phenomena such as intensity and totality of the experience. We conclude that the evidence for completeness in this group (from experimentals who took psilocybin) was strong, but not maximal.

The *third* group showed evidence that the phenomena of the mystical typology had been experienced, but not to the most complete degree possible. They did not have confirmation on the significance of the subcategory as a whole, nor on items which remained significant after "strong" score analysis from all methods of measurement. The content-analysis data usually were not significant. These subcategories were the less universal phenomenon of *deeply felt positive mood* (*love*), *persisting positive changes toward others* and *the experience, and sense of sacredness*.

Persisting positive changes in attitude and behavior toward others and toward the experience after six months, while not confirmed by the content-analysis, nevertheless have strong evidence from the follow-up questionnaire. Judged from the content analysis, these changes were apparently not so important to the subjects as changes toward self and life, but the subjects still indicated, when specifically asked on the follow-up questionnaire, that in ways such as more sensitivity and more authenticity toward others, and evaluation of the experience in terms of learning something considered personally very valuable, the experimentals scored significantly higher than the controls with "strong" scores. In addition, when all scores were used, other individual items from all the subcategories under persisting positive changes were significant, as has been discussed above. The weakest evidence for difference between experimentals and and controls was for the category, sense of sacredness. Even here the weight of evidence indicated that sacredness definitely was experienced more by the experimentals, as indicated from the post-drug and follow-up data in both the category as a whole and when only "strong" scores were used. The implicit kind of phenomena predominated, and awe (P56 and F22) was especially strong (see Table 35).

We should here distinguish between experimentals and controls in these categories which did not show evidence that the phenomena of the mystical typology had been experienced to the highest degree. In every category, subcategory, or individual item which contributed to a category or subcategory, the experimentals always had a higher total score than the controls, and no individual item was significant for the controls when only "strong" scores were used.

The controls did not experience the phenomena of the mystical typology to any degree of completeness. The subcategories in which the total scores of the controls were closest to the experimentals, were: blessedness and peace; sense of sacredness; love; and persisting changes toward others and toward the experience. These categories were the ones which were least significant (although *p* was still less than .055 in the majority of instances), and showed the most disagreement from the three methods of measurement. The design of the experiment suggests an explanation for the relatively high scores of the controls in these subcategories. In the case of sacredness, the meaningful religious setting of the experiment would naturally have encouraged such a response. The data from the questionnaires illustrated the difference in significance between explicit and implicit kinds of sacredness. Table 19 shows that the controls were closer to, although still below, the experimentals in total score for explicit phenomena than for implicit, in which the experimentals had significantly higher scores (*p* less than .02). In the case of love and changes toward others and toward the experience, observations by the controls of the profound experiences of the experimentals and interaction between the two groups on an interpersonal level were important parts of the experience for the controls. This fact was confirmed by the interviews after the experience.

The phenomena which the controls experienced most were among those which were experienced to the least degree of completeness by the experimentals. It can reasonably be assumed that the lack of significance for the experimentals in these categories was due to the experience of the phenomena by the controls, although at a lesser level of intensity and completeness, as was seen from frequency distributions of scores in Chapter VI.

External unity, on the other hand, was not experienced to any marked degree by the controls (mostly scores of "0"). The lack of significance, in this case in the content-analysis data, is assumed to be due to inadequate evidence from the accounts. The design of the experiment did not bring out this type of phenomenon. Individual meditation in a darkened chapel for the peak of the drug effect emphasized and nurtured internal rather than external experience.

From inspection of Table 35, it can be seen that for the subcategories which failed to be confirmed from all methods of measurement, the content analysis was usually the reason. This means that the judges felt that the personal accounts did not indicate "strong" or "most complete" experiences in these categories. Were they correct in their judgment? On the one hand, as judges who understood how each category was defined, they could give a more accurate score than subjects who were rating themselves on individual phenomenological items, but did not know what category was being measured. On the other hand, the judges were scoring only on the basis of second-hand reports. We must not make the assumption that each subject wrote down his complete experience. He might not have mentioned some particular phenomena because he did not think of it when he was writing his report, although we can assume that he reported what he thought was most important or what impressed him the most. Stace has pointed out that even the mystics did not write as much as we would have liked about the actual phenomenology of their experiences.[2] The questionnaires and interviews provided a check on this type of omission, and such evidence should not be ignored. It might be argued that the experimentals may have used "strong" scores indiscriminately on the questionnaires merely because their experiences were so unusual or intense. There was, however, a selective preference for certain items as can be seen from appendices C and D where the significance levels for all items in both questionnaires are listed. The score distributions listed in the tables in Chapter VI also showed that not all phenomena scored by the experimentals were rated "strong".

Individual reactions to the experience as a whole came out strongly in the interviews. Nine out of ten of the experimentals considered that their experience was significant and worthwhile and would be very willing, in fact eager, to try the experience again. Judged from the interviewer's perspective, eight out of ten of these experiences were predominantly positive, and had a pronounced significant and worthwhile effect in the lives of the persons involved, according to their own testimonies. One experimental had what he considered a worthwhile and significant experience from which he learned a great deal, but in regard to mystical phenomena his experience was not on the same level with the other eight. In his account and interview it was obvious that he had spent much of his time trying to remain in control and to interpret and intellectualize his experience. At one point he attempted to memorize Greek vocabulary-cards. After one such experience he was eager to have another chance to let himself go into the experience more completely without trying to resist the effects of the drug.

The tenth experimental subject had what he termed an interesting "psychological" and "aesthetic" experience for the first three-fourth of his experience, but then became frightened by loss of control and spent the remaining time in a terrifying fight to overcome the drug effects. He would not be interested in repeating the experience because his most predominant memory of the experience was that of fear. Six months later, in Part I of the followup questionnaire, he considered this fear-experience *slightly* harmful because "in a mob panic-situation, I feel I would be less likely to maintain a calm objective position than I might have formerly." During the interview he admitted that he had gone into the experience "as a psychological experiment" and had done

---

2. Stace, *op. cit.*, pp. 55-56.

no serious devotional preparation. His "inspirational" reading while the drug was taking effect consisted of studying some Psalms for a course in the Old Testament. His interpretation of his experience was a "psychotic episode."

The best indication of the reaction of the controls was the fact that they all were very eager for the opportunity to try psilocybin for themselves in the future. As far as their own experiences during the experiment were concerned, nine out of ten remarked in their accounts, in varying degrees of enthusiasm, about the meaningfulness of the setting in regard to the religious service. Because of the length of the service and the distractions from the experiences of others, only two out of the ten were able to keep from getting a little tired and/or bored. In the interviewer's opinion, only one of the controls had an experience which came anywhere near the level of mystical phenomena experienced by those who got psilocybin.

These subjective observations about the experimentals and controls are substantiated to some degree by certain items on the questionnaires. Within a few days after the experience (post-drug questionnaire data) the scores of experimentals were higher than those of controls for the degree to which the experience was considered both meaningful (P126) and religious or mystical (P127), but this difference only tended toward significance ($p = .062$). After six months, the usefulness of the experience (F56a) was significant at the .004 level and the value for life at the .02 level for the experimentals.
There was no significant difference between the two groups in their desire for more psilocybin experiences as indicated by F98a and F99a (p greater than .23 for both). This evidence was consistent with the fact that nineteen out of the twenty subjects wanted to volunteer for more experiments when questioned after six months.

Conclusions

Under the conditions of this experiment, those subjects who received psilocybin experienced phenomena which were indistinguishable from, if not identical with, certain categories defined by our typology of mysticism. The differences in completeness or intensity among the various categories have been discussed. Not all categories were experienced in the most complete way possible, although there was evidence that each category had been experienced to some degree.

In terms of our typology of mysticism, a "complete" mystical experience as a whole should have demonstrated the phenomena of all the categories in a complete way. The evidence from the content analysis (also supported by impressions from the interviews) showed that such perfect completeness of all categories was not experienced by the experimental subjects in contrast to the controls. The phenomena of internal unity, however, were experienced to a rather complete degree. Because unity is the heart of the mystical experience we might expect that phenomena of the other categories also should have been experienced to a complete degree as "by-products." In our data such a prediction was unquestionably correct for transcendence of time and space, transiency, paradoxicality, and persisting positive changes toward self and life. The evidence indicated a lesser degree of completeness in objectivity and reality, joy, and alleged ineffability; and a relatively greater lack in sense of sacredness, love, and persisting positive changes toward others and toward the experience. The experience of each of these last six subcategories could be termed incomplete to a more or less degree, but definitely present to some extent when compared to the controls. The experience as a whole, therefore, must be termed incomplete, in the strictest sense. It was remarkable, however, that so many phenomena of the mystical typology were experienced by our group of ten experimental subjects, none of whom were especially chosen other than by their own volunteering or had previous experience with psilocybin. While it is true that they were already committed to an interest in religion by the fact that they were all in a graduate school of theology, their middle-class, protestant backgrounds were rather non-mystical. Pre-drug testing indicated that there was no special tendency toward mysticism in personal experience or inclination except in the case of one or two.

The experience of the experimentals was certainly more like mystical experience than that of the controls who had the same expectation and suggestion from the preparation and setting. The most striking difference between the experimentals and controls was the ingestion of 30 mg of psilocybin, which it can be concluded was the facilitating agent responsible for the difference in phenomena experienced.

Although lacking in maximal completeness in some categories, the experimental evidence has strongly suggested that under the conditions described psilocybin can induce states of consciousness which are apparently indistinguishable from, if not identical with, those experienced by the mystics, according to their own descriptions. This conclusion gives support to the claims made by others who have used the same or similar drugs such as LSD or mescaline to aid in the induction of such experiences.

Such evidence can throw new light upon the psychological and biochemical mechanism which are at work in so-called "non-artificial" mystical experience. The biochemical equilibrium of the body and consequently of the mind should not be ignored in any serious study of mysticism. Ascetic practices such as fasting, sustained meditation, diet, restriction, sleep deprivation, flagellation and subsequent infection, sensory deprivation in caves or monastic cells, and breathing and postural exercises have an effect on biochemistry which in turn can produce psychological effects. Psychological conditioning also may influence body biochemistry. Psychology of religion needs to consider biochemical factors as well as psychological, social, cultural, economic, and political forces in the history, practice, and influence of mysticism.

Mystics have generally reported life-enhancing and -enriching effects from their experiences. It is now possible to test these claims by producing the phenomena of the experience and by observing behavior over a period of years in the lives of individuals. The evidence presented above indicated that over a short follow-up of six months, such claims seemed to be true. In addition, after four hours of follow-up interview with each subject, the experimenter was left with the overwhelming impression that the experience had made a profound impact (especially in terms of religious feeling and thinking) on the lives of eight out of ten of the experimental subjects. The control subjects were also impressed with the depth of the experiences of their friend who received psilocybin. These subjective impressions of those who intimately witnessed the experiment by participation and observation without the drug confirm the conclusion that profound and meaningful experiences occurred.

Let us consider more closely the pragmatic question of the lasting benefit or harm of the psilocybin experience and the kind of changes which were produced in individual lives. After six months the changes with the highest scores were all positive, and the experimental subjects attributed these changes to the drug experience. These data have indicated that although the psilocybin experience was quite unique and different from the "ordinary" reality of their everyday lives, the subjects felt that this experience enabled them to appreciate more deeply the meaning of their lives, to gain more depth and authenticity on ordinary living, and to rethink their philosophies of life and values. The data did not suggest that any "ultimate" reality was no longer important or meaningful. Each person who received psilocybin was motivated to integrate constructively what he had learned from his experience into his life-situation in his own way. The fact that the experience took place in the context of a worship service with the use of symbols which were familiar and meaningful to the participants was a help in this regard. Some persons found the music most significant, others the readings and spoken meditations, and still others the theological implications which they discerned themselves.

The continuing significance of the whole experience is perhaps best illustrated by what took place one year later during the next Easter season. Several of the subjects who had received psilocybin requested permission to listen to the tape of the Good Friday service. It was decided that this would be done in a chapel setting for any of the twenty subjects who were interested. Six of the seven students from the experimental group who were in the area attended while none out of nine control subjects did so. Several of the controls commented that they could not afford the time for such a lengthy service which had seemed too long the first time, although they indicated that they would have been quite eager to come if the chance to take psilocybin in such a setting had been offered. This reaction would seem to indicate that the lasting impact of the service was more meaningful to the psilocybin group than to the controls, although unconscious resentment against the experimenter from disappointment at not receiving the drug the first time could also have played a part. During the replay, reverent silence was maintained for the entire two-and-one-half-hour service. After the service, by their quiet demeanor, seriousness, and unenthusiasm for conversation at first, all six persons indicated the meaningfulness of the service for them. This was confirmed in the written accounts and discussion which followed. They all reported that the experience was helpful for integration and appreciation of what had taken place the previous year with psilocybin. The drug experience was not relieved in its original intensity or character, but many things which had been experienced previously on an unconscious level were now made conscious. The familiar and meaningful context was a great help in gaining benefit from both experiences. This follow-up study after one year has not been reported as a part of the data of the experiment because only part of the psilocybin group was involved, and there was no control group. What happened, however, gives some basis for the conclusion that the psilocybin experience in a religious context can provide the initial stimulus for an ongoing and lasting influence for the benefit of personal life, and that parts of the experience can be reactivated in the integration process without the further use of drugs.

Mysticism and *inner* experience have been stressed much more by Eastern religions than by Western. Perhaps Western culture is as far off balance in the opposite direction with its manipulation of the *external* world as exemplified by the emphasis on material wealth, control of nature, and admiration of science. Mysticism has been accused of fostering escapism from the problems of society, indifference to social conditions, and disinterest in social change. While the possibility of such excesses must always be remembered, our study has suggested the beneficial potential of mystical experience in stimulating the ability to feel and experience deeply and genuinely with the full harmony of both emotion and intellect. Such wholeness may have been neglected in modern Western society.

The relationship and relative importance of set, setting, and drug is a crucial question raised by our results. The fact that the controls had the same set and setting as the experimentals, but not the same experience, shows the utility of the drug as an important facilitating agent for the experimentals induction of mystical phenomena. Other investigators, however, report the predominance of unpleasant and "psychotomimetic" experiences rather than the majority of predominantly positive and mystical experiences which we witnessed.[3] The drugs in this case were comparable; the set and setting were not. Thus it would seem that the "drug effect" is a delicate combination of drug plus set and setting. The drug alone is not sufficient, and positive experiences are by no means automatic. A meaningful religious atmosphere has been shown to be one setting in which positive drug experiences can occur. The religious The religious context in our experiment appeared to give the psilocybin subjects a useful framework within which to derive meaning and integration from their experience both at the time and later. Our experience in this experiment has suggested that much forethought and preparation are needed to insure adequate set and setting although the precise qualitative and quantitative role of each factor has not been shown. For example, it must be pointed out that everything possible was done to maximize suggestion, but suggestion alone cannot account for the results because of the different experience of the control group. The hypothesis that suggestibility was heightened by psilocybin cannot be ruled out on the basis of our experiment. Although persuasive and similar to the explanation of mysticism by auto-suggestion,[4] this hypothesis still needs proof. An effort was made in our experiment to avoid suggesting the phenomena of the typology of mysticism, and the service itself made no such direct suggestion. Psychologists of religion by their interest in psychology and presumed religious sensitivity should be well-qualified to study the variables at work here.

Such research on the effect of the religious context on the psilocybin experience might illuminate the dynamics and significance of worship. Increased understanding of the psychological mechanisms involved might lead to more meaningful worship experiences for those who have not had the drug experience. Of course, there are various approaches to the theological significance of worship. This study was an empirical investigation, but we are aware that there are theological implications. The analogy to the efficacy of the sacraments would have to be considered. Furthermore, theologians must evaluate the light that such research could shed on the doctrine of Incarnation, the Holy Spirit, the presence of Christ, and of *gratia activa*. It must be kept in mind that we are only talking about the analogy or the elucidating suggestiveness of such drug research for a better psychological understanding of these theological concepts. Such considerations raise the question of the place of the emotional factor compared to the cognitive in religious worship. An even more basic question is the validity of religious experience of the mystical type on terms of religious truth. Reactions to these religious implications will vary with theological position and presuppositions, but one value of our study is to stimulate thoughtful examination of the problems.

Many unknown conscious and unconscious factors operate in mystical experience. Much investigation is needed in this area, and drugs like psilocybin can be a powerful tool. Experimental facilitation of mystical experience under controlled conditions can be an important method of approach to a better understanding of

mysticism. Better understanding can lead to appreciation of the role and place of such experiences in the history and practice of religion.

Chapter VIII
SUGGESTIONS FOR FURTHER RESEARCH AND IMPLICATIONS FOR THE FUTURE

This dissertation has demonstrated the potential of at least psilocybin, if not LSD and mescaline by analogy, as a tool for the study of the mystical state of consciousness. A program of future research with these chemicals in the psychology of religion can be divided into two different kinds, depending on the aim: (1) theoretical understanding and (2) social application in a religious context.

The first kind would be primarily theoretical and would have as its aim a more basic understanding of the psychology and phenomenology of mysticism. The method would be to approach the mystical state of consciousness as closely as possible under experimental conditions and to measure the effect of variables. This thesis has been a start toward this approach, but much work needs to be done in this area for a better understanding of mysticism from a physiological, biochemical, and psychological perspective.

Obviously, the first step in such a program would be to reproduce the same experiment with a different group of individuals who would be similar to the subjects already tested to check the repeatability and reliability of the results with the same design. This work should be done both by the same experimenter and by other independent experimenters with as much the same set and setting for the subjects as possible. The service itself has been taped and could be repeated exactly. The same experimental protocol, techniques for matching pairs, questionnaires, and tests could be used. Repetition of our experiment by different workers with other subjects would add to what has already been learned about the most effective way to design and run such experiments. A comparison of these data would further enlarge our understanding of the mystical state of consciousness.

From the work reported above certain interesting modifications can be suggested. If the effect of nicotinic acid plus psilocybin were first determined to be synergistic, antagonistic, or neutral, such a combination in the proper strength could be given to the experimentals while the controls received only nicotinic acid. A better double-blind control would be obtained from such a procedure because everyone would have the same initial reaction. To insure that bias from communication and observation of others would be reduced, the protocol could also be changed so that neither during nor after the experiment each participant would discuss his experience with the others. Subjects in such a case should not know each other outside the experiment, but his would detract considerably from the security and friendliness of the setting. Another perhaps more practical modification in design would be to administer the psilocybin and control substance at the beginning of the chapel service after an initial quiet period of personal meditation (perhaps for 15 to 30 minutes). The set and setting during the important time while the drug was taking effect would be that of serious worship in an actual service and would preserve unbroken a continuity which was disturbed when the groups moved into the chapel. With this change in the timing of the drug administration, either a longer service would have to be used, or when the service was over some type of supervised group interaction and exploration of interpersonal relations would have to be planned for the remaining time during which the psilocybin reaction would still be present (i.e., for two to three hours).

Preparation could be changed so that greater uniformity of expectancy would be achieved. A selected and uniform bibliography of mystical literature could be read and discussed by the groups to gain some familiarity with the kind of experience to be anticipated and to decrease the fear which sometimes occurs from a new and unexpected situation. This would provide a more uniform individual preparation. Also more meetings of the members of the groups with their leaders would increase rapport, mutual support, and sense of security. The practice of group meditation and worship would also aid this sense of togetherness and might make the experimental situation more natural. Experiments could be run with total fasting in advance for varying periods as part of the preparation. This would certainly insure more uniformity of the time of onset of the drug effects. Other ascetic practices such as sensory deprivation or sexual abstinence could be investigated for their influences. Another preparation factor to be tested would be the effect of being in a "state of grace" (i.e., prior absolution and restitution for any "sins" and guilt therefrom). The meaningfulness of the religious service for the leaders is another important variable. Their attitude and feeling might well add or detract from the sense of sacredness and seriousness which the subjects would feel in the experimental situation.

With adequate and appropriate pre-tests and enough subjects a correlation could be attempted between prior personality structure or religious experience and the types of drug reactions, both positive and negative. There was some very tentative suggestion in a few of our subjects that persons with a "mystical" temperament (i.e., those who already have experienced some mystical phenomena) are more likely to experience a degree of the mystical state of consciousness with the aid of psilocybin. Such an hypothesis could be tested by rigorous screening for subjects with such a temperament by interviews, psychological tests, and questionnaires. A double-blind study with the same experimental procedure as was used above could be run using only such screened subjects. Another method of screening would be to measure a prior, non-drug response to the taped chapel service as measured by questionnaire and interview. Only those subjects to whom such a service was meaningful and moving would be used in the drug experiment when the same service would be repeated at another time.

The success in producing states of consciousness which resemble, although incompletely, the mystical typology in prepared subjects with a single, initial dose of psilocybin encourages the trial of multiple sessions. The sheer uniqueness of the drug experience is overwhelming even to a well-prepared subject and may detract from his ability to let himself go completely and surrender to the experience. The hypothesis that familiarity with the experience positively reinforces set and setting and increases the likelihood of positive experience and mystical phenomena could be tested by repeating the psilocybin experience at regular intervals over a period of time (e.g., two, three, or four sessions in a year).[1] After the first session, single-blind controlled studies would be more practical than double-blind because of the very uniqueness of the experience. A matched control group could be run through repeated sessions at different times from the experimentals with as identical a set and setting as possible. Testing by interview and questionnaire could be done after each session to determine whether any new phenomenology had occurred which more closely resembled the mystical typology.
